

An anatomical illustration of the human torso, showing muscles, bones, and internal organs. The illustration is highly detailed, with various colors used to distinguish different structures. The heart is visible in the center, surrounded by major blood vessels. The lungs are on either side, and the rib cage is clearly defined. The overall style is realistic and scientific.

4TH CANADIAN EDITION

HUMAN PHYSIOLOGY

FROM CELLS TO SYSTEMS

SHERWOOD • WARD

BODY SYSTEMS

Made up of cells organized according to specialization to maintain homeostasis
See Chapter 1.

Each chapter begins with a system-specific version of the pictorial homeostatic model that depicts how the body system discussed in the chapter functions within the body as a whole. The accompanying icon marks a special section at each chapter's end that focuses on how the system contributes to homeostasis. Together these features will give you a better perspective on homeostasis and the interdependency of body systems.

To my family for all they have done for me in the
past, all they mean to me in the present,
and all I hope will yet be in the future:

My parents, Larry and Lee Sherwood
(both in memoriam)

My husband, Pater Marshall

My daughters and son-in-law, Melinda and Mark
Marple, Allison Tadros and Bill Krantz

My grandchildren, Lindsay Marple, Emily Marple,
Alexander Tadros, Lauren Krantz

Lauralee Sherwood

To my family for their love and support
and to the students whose quest
for knowledge has inspired me

Christopher Ward

Body Defences 459

Chapter 12

The Respiratory System 499

Chapter 13

The Urinary System 559

Chapter 14

Fluid and Acid–Base Balance 607

Chapter 15

The Digestive System 645

Chapter 16

Energy Balance and Temperature Regulation 699

Chapter 17

The Reproductive System 723

Appendix A

Système Internationale/Physiological Measurements A-1

Appendix B

A Review of Chemical Principles A-3

Appendix C

Storage, Replication, and Expression of Genetic
Information A-19

Appendix D

Principles of Quantitative Reasoning A-31

Appendix E

Answers to End-of-Chapter Objective Questions,
Quantitative Exercises, Points to Ponder, and Clinical
Considerations A-35

Appendix F

Reference Values for Commonly Measured Variables in
Blood and Commonly Measured Cardiorespiratory
Variables A-57

Appendix G

A Deeper Look into Chapter 12, The Respiratory
System A-59

Glossary G-1

Index I-1

Contents

Preface xvii

Chapter 1 | The Foundation of Physiology 3

1.1 Introduction to Physiology 3

- Approaches to understanding 4
- Structure and function 4

1.2 Levels of Organization in the Body 4

- Chemical level 4
- Cellular level 5
- Tissue level 6
- Organ level 7
- Body system level 7
- Organism level 8

1.3 Concepts of Homeostasis 9

- Homeostasis 9
- Body cells 9

Concepts, Challenges, and Controversies:

The Science and Direction of Stem Cell Research in Canada 10

- Body systems 11

1.4 Homeostatic Control Systems 14

- Local or body-wide control 14
- Negative feedback 14
- Positive feedback 15
- Feedforward mechanisms and anticipation 16
- Disruptions in homeostasis 16

Chapter in Perspective:

Focus on Homeostasis 16

Chapter Terminology 16

Review Exercises 17

Points to Ponder 18

Clinical Consideration 18

2.3 Cellular Metabolism 22

- Pathways for production of ATP 24
- Aerobic versus anaerobic conditions 28
- ATP production from other dietary sources 28
- ATP for synthesis, transport, and mechanical work 28

2.4 The Plasma Membrane 29

- Membrane structure and composition 29

Concepts, Challenges, and Controversies:

Cystic Fibrosis: A Fatal Defect in Membrane Transport 32

2.5 Cell-to-Cell Adhesions 34

- Biological glue 34
- Cell junctions 34

2.6 Overview of Membrane Transport 36

2.7 Unassisted Membrane Transport 37

- Passive diffusion of particles 37
- Passive diffusion of ions 38
- Osmosis 38

2.8 Assisted Membrane Transport 41

- Carrier-mediated transport 41
- Active or passive transport 43
- Vesicular transport 46
- Secretory vesicles 48
- Balance of endocytosis and exocytosis 50

2.9 Intercellular Communication and Signal Transduction 51

- Communication between cells 51
- Signal transduction 53
- Chemically gated channels 53
- Second-messenger pathways 53

2.10 Membrane Potential 54

- Separation of opposite charges 54
- Concentration and permeability of ions 54
- Specialized use of membrane potential in nerve and muscle cells 57
- Depolarization and hyperpolarization 58
- Electrical signals and ion movement 58

2.11 Graded Potentials 59

- Triggering events 59
- Graded potentials and passive currents 59
- Graded potentials and current loss 60

Chapter 2 | Cell Physiology 21

2.1 Observation of Cells 22

2.2 An Overview of Cell Structure 22

2.12 Action Potentials 61

- Reversal of membrane potential 61
- Changes in membrane permeability 62
- Restoration of concentration gradient 64
- Propagation of action potential 64
- Conduction via a nerve fibre 66
- One-way propagation 66
- The refractory period and the frequency of action potentials 69
- All-or-none fashion 69
- The strength of a stimulus and the frequency of action potentials 69
- Myelination and the speed of conduction 70
- Fibre diameter and the velocity of action potentials 70

Concepts, Challenges, and Controversies: Neural Stem Cells and Spinal Cord Repair 72

2.13 Regeneration of Nerve Fibres 72

- Schwann cells 72
- Oligodendrocytes 72
- Regeneration of cut central axons 73

2.14 Synapses and Neuronal Integration 74

- Synapses 74
- Neurotransmitters and signals 74
- Synapse behaviour 75

Why It Matters:

Summation of Neuronal Inputs 77

- Receptor combinations 77
- Neurotransmitter removal 77
- Grand postsynaptic potential 77
- Action potentials at the axon hillock 79
- Neuropeptides as neuromodulators 80
- Presynaptic inhibition or facilitation 81
- Drugs, diseases, and transmission 82
- Neurons: complex converging and diverging pathways 83

Chapter in Perspective:

Focus on Homeostasis 83

- Chapter Terminology 84
- Review Exercises 85
- Points to Ponder 87
- Clinical Consideration 88

3.3 Protection of the Central Nervous System 95

- Glial cells 95
- Astrocytes 95
- Oligodendrocytes 97
- Microglia 97
- Ependymal cells 98
- Protection of the delicate central nervous tissue 98
- Meningeal membranes: Wrapping, protecting, and nourishing 98
- Cerebrospinal fluid: A cushion for the brain 100
- The blood–brain barrier 100
- The role of oxygen and glucose 101

3.4 Spinal Cord 101

- The vertebral canal 101
- Spinal cord white matter 102
- Spinal cord grey matter 103
- Spinal nerves 103
- Basic reflexes 103

3.5 Brain Stem 109

- A vital link 110

3.6 Thalamus and Hypothalamus 112

- The thalamus 112
- The hypothalamus 113

3.7 Cerebral Cortex 113

Concepts, Challenges, and Controversies: Strokes: A Deadly Domino Effect 114

- The cerebral cortex: Grey matter and white matter 114
- Layers and columns in the cerebral cortex 114
- Lobes in the cerebral cortex 114
- The frontal lobes 115
- The parietal lobes 116
- Other brain regions and motor control 118
- Somatotopic maps 119
- Plasticity and neurogenesis of brain tissue 120
- Electroencephalograms 120
- Neurons 121

3.8 Cerebellum 121

- Balance and planning 121

3.9 Basal Ganglia 123

3.10 The Limbic System and Its Functional Relations with the Higher Cortex 124

- The limbic system and emotion 124
- The control of basic behavioural patterns 124
- Motivated behaviours 125
- Neurotransmitters in pathways for emotions and behaviour 125

3.11 Learning, Memory, and Language 126

- Learning 126
- Memory 126

Chapter 3 | The Central Nervous System 91

3.1 Organization of the Nervous System 92

- The central nervous system and the peripheral nervous system 92
- Three functional classes of neurons 92

3.2 Structure and Function of the Central Nervous System 93

Memory traces 128
Short-term and long-term memory: Different molecular mechanisms 128
Short-term memory 128
Long-term memory 130
Language 132
The association areas 133
The cerebral hemispheres 134

3.12 Sleep: An Active Process 134

EEG patterns during sleep 134
Behavioural patterns during sleep 135

Chapter in Perspective:

Focus on Homeostasis 136

Chapter Terminology 137

Review Exercises 138

Points to Ponder 139

Clinical Consideration 139

Chapter 4 | The Peripheral Nervous System: Sensory, Autonomic, Somatic 141

4.1 Introduction 141

4.2 The Peripheral Nervous System: Afferent Division 142

Fight-or-flight response 142
Somatosensation 142
Sensation: Internal and external 142
Perception: Conscious awareness of surroundings 143

4.3 Receptor Physiology 143

Adequate stimuli and threshold 143
Stimuli and receptor permeability 144
Receptor potentials and action potentials 144
Adaptation to sustained stimulation 145
Labelling somatosensory pathways 146

Why It Matters:

The Sense of Graded Potentials 146

Acuity, receptive field size, and lateral inhibition 147
Mechanoreceptors 147

4.4 Pain 149

Stimulation of nociceptors 149
The brain's built-in analgesic system 150

Concepts, Challenges, and Controversies: Acupuncture: Is It for Real? 152

4.5 Eye: Vision 152

Protective mechanisms and eye injuries 152
The eye: A fluid-filled sphere 153
The iris 154

Properties of light waves 155
The eye's refractive structures 156
Accommodation 157
The retinal layers 157
Photoreceptors 160
Properties of rods and cones 164
Sensitivity of the eyes to dark and light 164
Colour vision 165
Visual information 165
The thalamus and visual cortices 167
Visual input to other areas of the brain 169

4.6 Ear: Hearing and Equilibrium 169

Sound waves 169
The external ear 171
The tympanic membrane 172
The middle ear bones 172
The cochlea 172
Hair cells 173
Pitch discrimination 174
Loudness discrimination 174
The auditory cortex 176
Deafness 177
The vestibular apparatus 178

4.7 Chemical Senses: Taste and Smell 181

Taste receptor cells 181
Taste discrimination 182
Olfactory receptors in the nose 184
Detecting and sorting odour components 185
Odour discrimination 186
Adaptability of the olfactory system 186
The vomeronasal organ 186

4.8 The Peripheral Nervous System: Efferent Division 187

Fight-or-flight response 187

4.9 Autonomic Nervous System 187

Autonomic nerve pathways 188
Parasympathetic and sympathetic postganglionic fibres 188
Innervations of visceral organs 188
The adrenal medulla 192
Different receptor types 192
Control of autonomic activities 194

4.10 Somatic Nervous System 194

Motor neurons and skeletal muscle 194
Motor neurons: The final common pathway 195

4.11 Neuromuscular Junction 197

Linkage of motor neurons and skeletal muscle fibres 197
Acetylcholine 197

Acetylcholinesterase and acetylcholine activity 199
Vulnerability of the neuromuscular junction 199
Concepts, Challenges, and Controversies: Botulinum Toxin's Reputation Gets a Facelift 200

 **Chapter in Perspective:
Focus on Homeostasis 201**

Chapter Terminology 202
Review Exercises 204
Points to Ponder 206
Clinical Consideration 206

Chapter 5 | **Principles of Endocrinology: The Central Endocrine Glands 209**

5.1 General Principles of Endocrinology 209

Hormones 210
Plasma concentration 211
Transport, metabolism, and excretion 212
Endocrine disorders 213
Target cells 214

5.2 Principles of Hormonal Communication 214

Hydrophilic or lipophilic 214
The mechanisms of synthesis, storage, and secretion 216
Dissolving of hydrophilic hormones; transporting of lipophilic hormones 216
Hormones and intracellular proteins 217
Hydrophilic hormones and target proteins 217
Lipophilic hormones and protein synthesis 221

 Why It Matters 221

Hormonal responses versus neural responses 222

5.3 Comparison of the Nervous and Endocrine Systems 222

5.4 The Endocrine Tissues 222

5.5 Hypothalamus and Pituitary 225

The anterior and posterior glands 225
The hypothalamus and posterior pituitary 226
Relationship of the hypothalamus and posterior pituitary 227
Anterior pituitary hormones: Mostly tropic 227
Hypothalamic releasing and inhibiting hormones 227
Target-gland hormones 230

5.6 Endocrine Control of Growth 231

Growth hormone 232
Bone thickness and length 233
Somatomedins 235
Secretion 235

Concepts, Challenges, and Controversies:

Human Growth Hormone 236

Aberrant growth patterns 238
Other hormones 239

5.7 Pineal Gland and Circadian Rhythms 240

The suprachiasmatic nucleus 240

Concepts, Challenges, and Controversies: Tinkering with Our Biological Clocks 241

Melatonin 241

 **Chapter in Perspective:
Focus on Homeostasis 242**

Chapter Terminology 243
Review Exercises 244
Points to Ponder 244
Clinical Consideration 245

Chapter 6 | **The Endocrine Glands 247**

6.1 Thyroid Gland 248

Secretion of the thyroid hormone 248
Synthesis and storage of the thyroid hormone 248
Thyroglobulin-laden colloid 250
T₄ and T₃ 250
Thyroid hormone and basal metabolic rate 250
The hypothalamus–pituitary–thyroid axis 251
Abnormalities of thyroid function 252
Thyroid gland overstimulation 253
Parathyroid glands 254

6.2 Adrenal Glands 254

A steroid-secreting cortex and a catecholamine-secreting medulla 254
Mineralocorticoids, glucocorticoids, and sex hormones 254
Mineralocorticoids' major effects on Na⁺ and K⁺ balance 255
Glucocorticoids' metabolic effects 256
Cortisol secretion 257
The adrenal cortex and sex hormones 258
The adrenal cortex and hormone levels 258
The adrenal medulla 261
Epinephrine and norepinephrine 261
Epinephrine and the sympathetic nervous system 262
Sympathetic stimulation of the adrenal medulla 263

6.3 Integrated Stress Response 263

A general reaction to stress 263
The hypothalamus 265
Chronic psychosocial stressors 265

6.4 Endocrine Control of Fuel Metabolism 267

Fuel metabolism 267
Nutrients storage 268
The brain and glucose 269

The absorptive state and the postabsorptive state 270
Lesser energy sources 271
Insulin and glucagon 271
Insulin and blood glucose, fatty acid, and amino acid levels 272
Regulation of blood glucose levels 274
Diabetes mellitus 275
Hypoglycaemia 277

Concepts, Challenges, and Controversies: Diabetics and Insulin: Some Have It and Some Don't 278

Glucagon and insulin 280
Insulin and glucagon: A team 281
Glucagon excess and diabetes mellitus 281
Epinephrine, cortisol, and growth hormone 281

6.5 Endocrine Control of Calcium Metabolism 284

Plasma Ca^{2+} 284
Control of Ca^{2+} metabolism 284
Parathyroid hormone and free plasma Ca^{2+} levels 285
Bone remodelling 285
Mechanical stress 286
PTH and plasma Ca^{2+} 286
PTH and Ca^{2+} transfer 286
PTH and localized dissolution of bone 288
PTH and the kidneys 288
PTH and intestinal absorption of Ca^{2+} and PO_4^{3-} 289
Plasma concentration of free Ca^{2+} : Regulating PTH secretion 289
Calcitonin and plasma Ca^{2+} concentration 289
Vitamin D and calcium absorption 289
Phosphate metabolism 290
Disorders in Ca^{2+} metabolism 291

 Chapter in Perspective: Focus on Homeostasis 292

Chapter Terminology 293
Review Exercises 294
Points to Ponder 295
Clinical Consideration 295

chapter 7 | Muscle Physiology 297

7.1 Introduction 297

7.2 Structure of Skeletal Muscle 298

Skeletal muscle fibres 298
Myosin 300
Actin, tropomyosin, and troponin 301

7.3 Molecular Basis of Skeletal Muscle Contraction 302

Cross bridges 303
Excitation–contraction coupling 304

 Why It Matters: Rigor Mortis 307

Contractile activity 308

7.4 Skeletal Muscle Mechanics 309

Whole muscles 309
Muscle contractions 309
Motor unit recruitment 309
Frequency of stimulation 310
Twitch summation at the cellular level 312
Optimal muscle length 312
Muscle tension and bone 313
Isotonic and isometric contractions 314
Dynamic and static contractions 314
Velocity of shortening 315
Heat 316
Skeletal muscles, bones, and joints 316

 Why It Matters 317

7.5 ATP and Fibre Types 317

Contractile use of ATP 317
Fatigue 317
Muscle fibre types within a single motor unit 318
Muscle fibre adaptation (plasticity) 320

 Why It Matters: The Benefits of Resistance Training 320

Concepts, Challenges, and Controversies: Muscular Dystrophy: When One Small Step Is a Big Deal 322

7.6 Control of Motor Movement 322

Neural input 323
Afferent information 325

7.7 Smooth and Cardiac Muscle 326

Multiunit smooth muscle 328
Single-unit smooth muscle cells and functional syncytia 328
Smooth muscle cells: Small and unstriated 329
Smooth muscle cells and calcium 329
Single-unit smooth muscle: Myogenic 330
Gratation of single-unit smooth muscle contraction 332
Smooth muscle: Tension and relaxation 333
Smooth muscle: Slow and economical 334
Cardiac muscle 334

 Chapter in Perspective: Focus on Homeostasis 334

Chapter Terminology 335
Review Exercises 336
Points to Ponder 337
Clinical Consideration 338

Integration of Human Physiology: Movement and Parkinson's Disease 339

chapter 8 | Cardiac Physiology 345

8.1 Introduction 345

8.2 Anatomy of the Heart 346

A dual pump 346

Why It Matters: CPR 347

- Pressure-operated heart valves 347
- The heart walls 350
- Cardiac muscle fibres 350
- The pericardial sac 351

8.3 Electrical Activity of the Heart 352

- Cardiac autorhythmic cells 352
- The sinoatrial node 352
- Cardiac excitation 354
- Cardiac contractile cells 355
- Calcium release from the sarcoplasmic reticulum 356
- Long refractory period 357
- The ECG 357
- The ECG record 358
- The ECG diagnosis 359

8.4 Mechanical Events of the Cardiac Cycle 361

- Contracting and relaxing 361
- Heart sounds 364

8.5 Cardiac Output and its Control 365

- Cardiac output 365
- Heart rate 365
- Stroke volume 367
- Increased end-diastolic volume 368
- Sympathetic stimulation 369

Why It Matters: High Blood Pressure 370

- Heart failure 371

8.6 Nourishing the Heart Muscle 373

- The heart's blood supply 373
- Atherosclerotic coronary artery disease 374

Concepts, Challenges, and Controversies: Atherosclerosis: Cholesterol and Beyond 376

Chapter in Perspective: Focus on Homeostasis 379

- Chapter Terminology 380
- Review Exercises 380
- Points to Ponder 382
- Clinical Consideration 382

Chapter 9 | Vascular Physiology 385

9.1 Introduction 386

- Maintenance of homeostasis 386
- Blood flow and the pressure gradient 386
- The vascular tree 388
- The structure of blood vessels 388

9.2 Arteries 389

- Rapid-transit passageways and pressure reservoirs 389

Concepts, Challenges, and Controversies: From Humours to Harvey: Historical Highlights in Circulation 390

- Arterial pressure and diastole 391
- Blood pressure can be measured using a
sphygmomanometer 392
- Mean arterial pressure 394

9.3 Arterioles 394

- The major resistance vessels 394
- Arteriolar radius 396
- Local influences on arteriolar radius 396
- Local histamine release 399

Why It Matters: Local Heat or Cold Application 399

- Local physical influences 399
- Extrinsic sympathetic control of arteriolar radius 400
- The medullary cardiovascular control centre 402

9.4 Capillaries 402

- Capillaries: Sites of exchange 403
- Capillary pores 405
- Capillaries under resting conditions 406
- Interstitial fluid: A passive intermediary 407
- Diffusion across the capillary walls 408
- Bulk flow across the capillary walls 409
- The lymphatic system 411
- Oedema and interstitial fluid accumulation 413

9.5 Veins 414

- Venules 414
- Veins: A blood reservoir 414
- Venous return 414

9.6 Blood Pressure 419

- Blood pressure regulation 419
- The baroreceptor reflex 420
- Other reflexes and responses 421
- Hypertension 424
- Prehypertension 425
- Orthostatic hypotension 425
- Circulatory shock 426

Chapter in Perspective: Focus on Homeostasis 428

- Chapter Terminology 429
- Review Exercises 429
- Points to Ponder 431
- Clinical Consideration 431

Chapter 10 | The Blood 433

10.1 Introduction 433

10.2 Plasma 434

- Plasma water 434
- Plasma proteins 435

10.3 Erythrocytes 436

- Structure and function 436
- Bone marrow 437
- Erythropoietin 438
- Blood types 438
- Anaemia 441
- Polycythaemia 441

Concepts, Challenges, and Controversies: In Search of a Blood Substitute 442

10.4 Leukocytes 444

- Defence agents 445
- Five types 445
- Production 445

10.5 Platelets and Haemostasis 447

- Platelets 448
- Haemostasis 448
- Vascular spasm 448
- Platelet aggregation 448
- Clot formation 449
- Fibrinolytic plasmin 452
- Inappropriate clotting 453
- Haemophilia 453

Chapter in Perspective: Focus on Homeostasis 454

- Chapter Terminology 454*
- Review Exercises 455*
- Points to Ponder 456*
- Clinical Consideration 456*

Chapter 11 | Body Defences 459

11.1 Introduction 460

- Pathogenic bacteria and viruses 460

11.2 External Defences 460

- Epidermis 461
- Dermis 461
- Skin's exocrine glands and hair follicles 462
- Hypodermis 462
- Specialized cells 462

Why It Matters: Protection from UV Light 463

- Protective measures 463

11.3 Internal Defences 464

- Leukocytes 464
- Immune responses 465

11.4 Innate Immunity 466

- Inflammation 466
- NSAIDs and glucocorticoids 471
- Interferon and viruses 471

Natural killer cells 472

The complement system 473

11.5 Adaptive Immunity: General Concepts 473

- Antibody-mediated immunity and cell-mediated immunity 473
- Antigens 474

11.6 B Lymphocytes: Antibody-Mediated Immunity 475

- Plasma cells 475
- Antibody subclasses 475
- Antibody structure 476
- Antibodies and immune responses 477
- Neutralization and agglutination 477
- Clonal selection 478
- Selected clones 479

Concepts, Challenges, and Controversies: Vaccination: A Victory over Many Dreaded Diseases 480

- B cells and gene fragments 481
- Active and passive immunity 481

11.7 T Lymphocytes: Cell-Mediated Immunity 482

- T cells and targets 482
- Cytotoxic T cells, helper T cells, and regulatory T cells 482
- Cytotoxic T cells 483
- Helper T cells 485
- The immune system and self-antigens 486
- Autoimmune diseases 486
- The major histocompatibility complex 487
- Immune surveillance 489
- Regulatory loops 491

11.8 Immune Diseases 491

- Immunodeficiency 491
- Allergies 491

Chapter 12 | The Respiratory System 499

12.1 Introduction 499

- External respiration 500
- Anatomy of the respiratory system 501

Why It Matters 505

12.2 Respiratory Mechanics 505

- Pressures in the respiratory system 505
- Mechanical properties of the respiratory system 505

Why It Matters: Emphysema 509

Alveolar stability 509
How alveolar pressure changes 511
Airway resistance and airflow 514
Airway resistance and chronic pulmonary diseases 516
Lung volumes and capacities 517
Pulmonary and alveolar ventilation 521
Work of breathing 522

12.3 Gas Exchange 523

Diffusion at the alveolar–capillary membrane 524
Partial pressure gradients 524
Other factors 527
Regional control of ventilation and perfusion 529

12.4 Gas Transport 531

Blood, oxygen, and haemoglobin 531
 P_{O_2} and haemoglobin saturation 532
Haemoglobin and oxygen transfer 534
Unloading of oxygen 535
Haemoglobin and carbon monoxide 537
Carbon dioxide 537
Abnormal blood-gas levels 539

Why It Matters:

Dangers of Supplemental Oxygen 541

12.5 Control of Breathing 541

Respiratory centres in the brain 541
Influences from higher centres 542
Control of respiratory pattern 543
Acid–base balance 548
Effect of exercise on ventilation 549
Other factors that may increase ventilation during exercise 550
Apnea and dyspnea 550

Chapter in Perspective:

Focus on Homeostasis 551

Chapter Terminology 551
Review Exercises 552
Points to Ponder 554
Clinical Consideration 554

Integration of Human Physiology: Exercise and Obstructive Sleep Apnea 555

13.3 Glomerular Filtration 566

The glomerular membrane 566
Glomerular capillary blood pressure 567
Changes in GFR 568
The GFR and the filtration coefficient 572
The kidneys and cardiac output 572

13.4 Tubular Reabsorption 573

Highly selective and variable 573
Transepithelial transport 574
The $Na^+ - K^+$ ATPase pump 575
Aldosterone and Na^+ reabsorption 575
Atrial natriuretic peptide and reabsorption 578
Glucose and amino acids 579
Actively reabsorbed substances 579
Glucose and the kidneys 579
Phosphate and the kidneys 580
Responsibility of Na^+ reabsorption for Cl^- , H_2O , and urea reabsorption 581
Unwanted waste products 582

13.5 Tubular Secretion 583

Hydrogen ion secretion 583
Potassium ion secretion 583
Organic anion and cation secretion 584
Summary of reabsorptive and secretory processes 585

13.6 Urine Excretion and Plasma Clearance 585

Plasma clearance: Volume 586
Plasma clearance rate if a substance is filtered but not reabsorbed 586
Plasma clearance rate if a substance is filtered and reabsorbed 586
Plasma clearance rate if a substance is filtered and secreted but not reabsorbed 588
The kidneys and urine of varying concentrations 588
The medullary vertical osmotic gradient 589
Vasopressin-controlled H_2O reabsorption 592
Countercurrent exchange within the vasa recta 595
Water reabsorption 595
Renal failure 596
Urine storage 597

Concepts, Challenges, and Controversies: Dialysis: Cellophane Tubing or Abdominal Lining as an Artificial Kidney 599

Chapter 13 | The Urinary System 559

13.1 Introduction 559

The kidneys 560
The kidneys and urine 560
The nephron 561

Why It Matters:

The Nephron 564

The three basic renal processes 564

13.2 Renal Blood Flow 565

Chapter 14 | **Fluid and Acid–Base Balance 607**

14.1 Balance Concept 608

- The internal pool of a substance 608
- Maintenance of a balanced ECF constituent 608

14.2 Fluid Balance 609

- Body water distribution 609
- Plasma and interstitial fluid 610
- ECF volume and osmolarity 611
- Control of ECF volume 611
- Control of salt 612
- Control of ECF osmolarity 613
- ECF hypertonicity and shrinking cells 614
- ECF hypotonicity and swelling cells 614

Why It Matters:

The Importance of Vasopressin 615

- Vasopressin secretion and thirst: Largely triggered simultaneously 617

14.3 Acid–Base Balance 620

- Acids liberate H^+ ; bases accept them 620
- The pH designation 620

Concepts, Challenges, and Controversies: Acid–Base Balance: The Physico-chemical Approach 621

- Hydrogen ions 622
- Chemical buffer systems 623
- The $H_2CO_3:HCO_3^-$ buffer pair 624
- The protein buffer system 625
- The haemoglobin buffer system 625
- The phosphate buffer system 625
- Chemical buffer systems: The first line of defence 626
- The respiratory system and $[H^+]$ 626
- The respiratory system: The second line of defence 627
- The kidneys and plasma pH control 627
- The kidneys and HCO_3^- excretion 628

Why It Matters:

Acid–Base Balance in Cystic Fibrosis 630

- The kidneys and ammonia 630
- The kidneys: A powerful third line of defence 632
- Acid–base imbalances 632
- Respiratory acidosis and an increase in $[CO_2]$ 632
- Respiratory alkalosis and a decrease in $[CO_2]$ 634
- Metabolic acidosis and a fall in $[HCO_3^-]$ 634
- Metabolic alkalosis and an elevation in $[HCO_3^-]$ 635

Index I-1

Preface

Goals, Philosophy, and Theme

Our goal in writing physiology textbooks is to help students not only learn about how the body works but also to share our enthusiasm for the subject matter. We have been teaching physiology for over 40 years and remain awestruck at the intricacies and efficiency of body function. No machine can perform even a portion of natural body function as effectively. Most of us, even infants, have a natural curiosity about how our bodies work. When a baby first discovers it can control its own hands, it is fascinated and spends many hours manipulating them in front of its face. By capitalizing on students' natural curiosity about themselves, we try to make physiology a subject they can enjoy learning.

Even the most tantalizing subject can be difficult to comprehend if not effectively presented, however. Therefore, this book has a logical, understandable format with an emphasis on how each concept is an integral part of the entire subject. Too often, students view the components of a physiology course as isolated entities; by understanding how each component depends on the others, a student can appreciate the integrated functioning of the human body. The text focuses on the mechanisms of body function from cells to systems and is organized around the central theme of *homeostasis*—how the body meets changing demands while maintaining the internal constancy necessary for all cells and organs to function. The text is written in simple, straightforward language, and every effort has been made to ensure smooth reading through good transitions, common-sense reasoning, and integration of ideas throughout.

This text is designed for undergraduate students preparing for health-related careers, but its approach and depth are also appropriate for other undergraduates. Because this book is intended as an introduction and, for most students, may be their only exposure to a formal physiology text, all aspects of physiology receive broad coverage; yet depth, where needed, is not sacrificed. The scope of this text has been limited by judicious selection of pertinent content that a student can reasonably be expected to assimilate in a one-semester physiology course. Materials were selected for inclusion on a “need to know” basis, so the book is not cluttered with unnecessary detail. Instead, content is restricted to relevant information needed to understand basic physiological concepts and to serve as a foundation for later more in-depth studies of selected aspects of physiology and related health sciences, as well as in the health professions. Some controversial ideas and hypotheses are presented to illustrate that physiology is a dynamic, changing discipline.

To keep pace with today's rapid advances in the health sciences, students in the health professions must be able to draw on

their conceptual understanding of physiology instead of merely recalling isolated facts that soon may be out of date. Therefore, this text is designed to promote understanding of the basic principles and concepts of physiology rather than memorization of details.

In consideration of the clinical orientation of most students, research methodologies and data are not emphasized, although the material is based on up-to-date evidence. New information based on recent discoveries has been included throughout. Students can be assured of the timeliness and accuracy of the material presented. To make room for new, pertinent information, we have carefully trimmed content while clarifying, modifying, and simplifying as needed to make this edition fresh, reader-friendly, and current.

Because the function of an organ depends on the organ's construction, enough relevant anatomy is integrated within the text to make the inseparable relation between form and function meaningful.

Organization

There is no ideal organization of physiologic processes into a logical sequence. With the sequence we chose for this book, most chapters build on material presented in immediately preceding chapters, yet each chapter is designed to stand alone, allowing the instructor flexibility in curriculum design. This flexibility is facilitated by cross-references to related material in other chapters. The cross-references let students quickly refresh their memory of material already learned or to proceed, if desired, to a more in-depth coverage of a particular topic.

The general flow is from introductory information on cells and metabolism, to excitable tissue, to organ systems. We have tried to provide logical transitions from one chapter to the next. For example, Chapter 7, Muscle Physiology, ends with a discussion of cardiac muscle, which is carried forward in Chapter 8, Cardiac Physiology. Even topics that seem unrelated in sequence, such as Chapter 11, Body Defences, and Chapter 12, The Respiratory System, are linked together, in this case by discussion of the respiratory system's contribution to protection against inhaled viruses and particles.

Several organizational changes have been made, which we believe will enhance the students' understanding of human physiology and the readability of the text. For example, we have included three inserts called the Integration of Human Physiology. Each insert focuses on the integration of a number of body systems, to aid the instructor in teaching integrative physiology. Again, these inserts were designed to stand alone.

The first insert, for example, discusses the concept of locomotion, and contrasts locomotion in a healthy person with the problems associated with locomotion when disease disrupts normal neural communication. Each of the three integrative inserts is strategically placed, following the chapters upon which they build.

We have also placed the chapters discussing the nervous and endocrine systems near the beginning of the textbook. The decision to place these chapters in close proximity and near the start of the text was made based on the belief that it is important for the student to understand how communication takes place within the human body, as communication has a considerable influence on homeostasis.

More specific hormones are subsequently introduced in appropriate chapters, such as vasopressin and aldosterone in the chapters on the kidneys (Chapter 13) and fluid balance (Chapter 14). Intermediary metabolism (Chapter 2) of absorbed nutrient molecules is largely under endocrine control, providing a link from digestion (Chapter 15) and energy balance (Chapter 16) to the endocrine chapters. Chapter 6, The Endocrine Glands, pulls together the source, functions, and control of specific endocrine secretions discussed in Chapter 5, Principles of Endocrinology, and serves as a unifying capstone for homeostatic body function. Finally, building on the gonadotropic hormones introduced in Chapter 6, Chapter 17 diverges from the theme of homeostasis to focus on reproductive physiology.

Besides the novel handling of hormones and the endocrine system, other organizational features are unique to this book. Unlike other physiology texts, the skin is covered in the chapter on body defences (Chapter 11), in consideration of the skin's newly recognized immune functions. Bone is also covered more extensively in the endocrine chapter than in most undergraduate physiology texts, especially with regard to hormonal control of bone growth and bone's dynamic role in calcium metabolism.

A concerted effort was made to bolster specific topics in each chapter. The following are some examples of this. The cell physiology chapter (Chapter 2) has been expanded and includes an introduction to excitable cells and neurons. The central nervous system (Chapter 3) has an expanded discussion on somatosensory mapping and plasticity of the motor cortex, and it introduces the Babinski reflex. In the following chapter, The Peripheral Nervous System, the topic of somatosensory mapping is carried forward from Chapter 3, and a more detailed discussion of mechanoreceptors has been included, as well as an introduction to the fight-or-flight response.

Also new to this edition is the inclusion of a feature called **Clinical Connections**. The beginning of most chapters has an introduction to a clinical case that is related to the content of the chapter. As you move through the chapter, this case is revisited to put the underlying physiology into context.

Departure from traditional groupings of material in several important instances has permitted more independent and more extensive coverage of topics that are frequently omitted or buried within chapters concerned with other subject matter. For example, a separate chapter (Chapter 14) is devoted to fluid balance and acid–base regulation, topics often included in the kidney chapter. Further, we have grouped energy balance and temperature regulation into an independent chapter (Chapter 16).

Although there is a rationale for covering the various aspects of physiology in the order given here, it is by no means the only logical way to present each topic. Each chapter is able to stand alone, especially with the cross-references provided, so that the sequence of presentation can be varied at the instructor's discretion. Some chapters may even be omitted, depending on the students' needs and interests and the time constraints of the course. For example, a cursory explanation of the defensive role of the leukocytes appears in the chapter on blood, so an instructor can choose to omit the more detailed explanations of immunity in Chapter 11, Body Defences.

Lauralee Sherwood and Christopher Ward

For the Canadian Edition

The fourth Canadian edition of *Human Physiology: From Cells to Systems* has been substantially revised to meet the needs of Canadian students and instructors in core physiology programs, as well as related programs such as kinesiology, nursing, physical therapy, and zoology, where physiology represents an important component of the curriculum. The reorganization of the text has allowed for the inclusion of integrative physiology sections to assist the instructor in addressing this component of their course. A continued effort has been made by the authors to highlight topics of research important to Canadians, and to include statistics, organizations, and researchers from Canadian schools, institutes, and hospitals. The *Système international d'unités* (SI) and Canadian spelling have been used throughout. In addition to these changes, this fourth Canadian edition also provides students and instructors with updated physiological concepts, new figures and tables, new trends in physiological research, and current and relevant examples of the body's function in disease, exercise, and health. The end-of-chapter review questions have been retooled to the individual chapter's objectives. As well, the Nelson Education Testing Advantage (NETA) program was used to ensure high-quality test banks.

New to the Fourth Canadian Edition

Global changes to this edition

- Updated references to Canadian research
- Timely material incorporated throughout
- Over 280 figures, which include examples of extensively revised, and newly conceptualized ideas
- Every opportunity used to make the writing as clear, concise, well-organized, and relevant for readers as possible
- The inclusion of Clinical Connections feature to most chapters

Chapter 1—The Foundation of Physiology

- Updated references to Canadian research
- Updated information on stem cells

Chapter 2—Cell Physiology

- Updated discussion of neurons
- Expanded discussion on membrane potential and cellular communication

Chapter 3—The Central Nervous System

- Condensed and focused content on the CNS
- Reorganized the order of discussion of the CNS

Chapter 4—The Peripheral Nervous System: Sensory, Autonomic, Somatic

- Enhanced clarity for some content

Chapter 5—Principles of Endocrinology: The Central Endocrine Glands

- Streamlined content

Chapter 6—The Endocrine Glands

- This chapter repositioned to follow the chapter on the central endocrine glands
- Updated content

Chapter 7—Muscle Physiology

- Enhanced clarity of key concepts

Chapter 8—Cardiac Physiology

- Included discussion on how afterload affects stroke volume

Chapter 9—Vascular Physiology

- Updated discussion
- Clarified some key concepts

Chapter 10—The Blood

- Updated and clarified content

Chapter 11—Body Defences

- Updated content
- Streamlined content
- Enhanced clarity of discussion

Chapter 12—The Respiratory System

- Streamlined content
- Enhanced clarity of discussion

Chapter 13—The Urinary System

- Streamlined topic discussion

Chapter 14—Fluid and Acid–Base Balance

- Clinical case on diabetic ketoacidosis (DKA) to highlight the clinical relevance of fluid balance and acid–base regulation

- New brief discussion on the two types of diabetes insipidus (nephrogenic and central) as they relate to vasopressin
- Addition of new figures, including $\text{Na}^+ - \text{H}^+$ exchanger of the proximal nephron and a nomogram to help diagnose acid–base disorders

Chapter 15—The Digestive System

- Updated content

Chapter 16—Energy Balance and Temperature Regulation

- Updated to include current statistics

Chapter 17—The Reproductive System

- Updated content

In addition, pedagogical features unique to the fourth Canadian edition of *Human Physiology: From Cells to Systems* include a new addition: **Clinical Connections** have been added to most chapters. This feature serves to relate diseases and their symptoms to what is happening in the underlying physiology. The **Further Reading** list of relevant research articles from international journals within the **Concepts, Challenges, and Controversies** boxes is intended to facilitate further study, and the **Chapter Terminology** list of relevant key terms at the end of each chapter is available for students to review. **Why It Matters** boxes have been added to some chapters to draw attention to the importance of material that at first glance may appear trivial. The **Table of Contents** has been simplified to allow for easier navigation of the text, as have the **section headings** within each chapter. **Appendixes**, which include Reference Values for Commonly Measured Variables in Blood and Commonly Measured Cardiorespiratory Variables, and the **Glossary** have been expanded to accommodate new physiology concepts.

Text Features and Learning Aids

Implementing the homeostasis theme

A unique, easy-to-follow schematic of the relations between cells and systems to illustrate homeostasis is developed in the introductory chapter and presented on the inside front cover as a quick reference. Each chapter begins with its own quick reference, accompanied by a brief, written introduction emphasizing how the body system considered in the chapter functionally fits in with the body as a whole. This opening feature is designed to orient students to the homeostatic aspects of the material that follows. Then, at the close of each chapter, the **Chapter in Perspective: Focus on Homeostasis** is intended to put into perspective how the part of the body just discussed contributes to homeostasis. This capstone feature, the opening homeostatic model, and the introductory comments are designed to work together to facilitate comprehension of the interactions and interdependency of body systems, even though each system is discussed separately.

Analogies

Many analogies and frequent references to everyday experiences are included to help students relate to the physiology

concepts presented. These useful tools have been drawn in large part from Lauralee Sherwood's four decades of teaching experience. Knowing which areas are likely to give students the most difficulty, she has tried to develop links that help them relate the new material to something with which they are already familiar.

Pathophysiology and clinical coverage

Another effective way to keep students' interest is to help them realize they are learning worthwhile and applicable material. Because most students using this text will have health-related careers, frequent references to pathophysiology and clinical physiology demonstrate the content's relevance to their professional goals. *Clinical Note* icons flag clinically relevant material featured throughout the text.

Check Your Understanding

Check Your Understanding questions serve as study breaks for students to test their knowledge before continuing with more material. These questions are different than the **Written Questions** that cover the same content at the end of the chapter. Many of the new section questions involve doing something other than copying an answer from a text description, such as drawing and labelling, preparing a chart, predicting based on information provided, and so on.

Boxed features

Two types of boxed features are integrated within the chapters, and in most cases they conclude with a list of journal articles and references pertinent to the topic. As much as possible, the journal articles and references are Canadian.

Concepts, Challenges, and Controversies boxes expose students to high-interest, tangentially relevant information on such diverse topics as stem cell research, acupuncture, new discoveries regarding common diseases such as strokes, historical perspectives, and body responses to new environments such as those encountered in space flight and deep-sea diving.

The **Why It Matters** boxes can be used by students and instructors to help glean the importance of, for example, a seeming simple reaction, shedding light on how something small and apparently insignificant can in actuality have an impact on large-scale system-wide function.

The **Integration of Human Physiology** pages are intended to enrich the understanding of the issues covered within the chapters. These pages are distinct and easy to find due to their purple background and dark purple edges. They build on the concepts introduced within the chapters and complement the physiological processes presented. These pages are included to highlight both the normal physiological responses and the abnormal physiological responses to stimuli, such as movement, altitude, and exercise.

Pedagogical illustrations

The anatomic illustrations, schematic representations, photographs, tables, and graphs are designed to complement and reinforce the written material. Unique to this book are the numerous

process-oriented figures with step-by-step descriptions, which provide a concise visual aid for understanding the processes.

Flow diagrams are used extensively to help students integrate the written information. In the flow diagrams, light and dark shades of the same colour denote a decrease or an increase in a controlled variable, such as blood pressure or the concentration of blood glucose.

Integrated, colour-coded figure/table combinations help students better visualize what part of the body is responsible for what activities. For example, the anatomic depiction of the brain is integrated with a table of the functions of the major brain components, with each component shown in the same colour in the figure and the table.

A unique feature of this book is that people depicted in the various illustrations are realistic representatives of a cross-section of humanity (they were drawn based on photographs of real people). Sensitivity to various races, sexes, and ages should enable all students to identify with the material being presented.

Key terms and word derivations

In most cases, key terms are defined as they appear in the text. These terms are key to understanding the concepts outlined within each chapter. A chapter terminology section also appears at the end of each chapter. Many key terms are also found in the glossary.

End-of-chapter learning and review

A **Chapter Terminology** list of relevant key terms appears at the end of each chapter for students to review. The **Review Exercises** at the end of each chapter include a variety of question formats for students to self-test their knowledge and application of the facts and concepts presented. Also available are **Quantitative Exercises** that provide the students with an opportunity to practise calculations that will enhance their understanding of complex relationships. A **Points to Ponder** section features thought-provoking problems that encourage students to analyze what they have learned, and the **Clinical Consideration**, a mini case history, challenges them to apply their knowledge to a patient's specific symptoms. Answers and explanations for all of these questions are found in Appendix E.

Appendixes, Glossary, and Study Cards

The appendixes are designed for the most part to help students brush up on some foundation material they are assumed to have studied in prerequisite courses.

- **Appendix A, Système international d'unités (SI)**, is a conversion table between metric measures and their Imperial equivalents.
- Most undergraduate physiology texts have a chapter on chemistry, yet physiology instructors rarely teach basic chemistry concepts. Knowledge of chemistry beyond that introduced in secondary schools is not required for understanding this text. Therefore, to reserve valuable text space for discussion of physiology concepts, we have provided **Appendix B, A Review of Chemical Principles** as a handy reference for the review of basic chemistry concepts that apply to physiology.

- Likewise, **Appendix C, Storage, Replication, and Expression of Genetic Information**, can serve as a reference for students and, when appropriate, be used by the instructor as assigned material. It includes a discussion of DNA and chromosomes, protein synthesis, cell division, and mutations.
- **Appendix D, Principles of Quantitative Reasoning**, is designed to help students become more comfortable working with equations and translating back and forth between words, concepts, and equations. This appendix supports the Quantitative Exercises in the end-of-chapter material.
- **Appendix E, Answers to End-of-Chapter Objective Questions, Quantitative Exercises, Points to Ponder, and Clinical Considerations**, provides answers to all objective learning activities, solutions to the Quantitative Exercises, and explanations for the Points to Ponder and Clinical Considerations.
- **Appendix F, Reference Values for Commonly Measured Variables in Blood and Commonly Measured Cardiorespiratory Variables**, provides normal male and female values.
- **Appendix G, A Deeper Look into Chapter 11: The Respiratory System**, provides greater detail on the terminology and gas laws covered in Chapter 11.
- The **Glossary**, which offers a way to review the meaning of key terminology, includes phonetic pronunciations of the entries.
- The **Study Cards** present the major points of each chapter in concise, section-by-section bulleted lists, including cross-references for page numbers, figures, and tables. With this summary design, students can review more efficiently by using both written and visual information to focus on the main concepts.

About the Nelson Education Teaching Advantage (NETA)

The Nelson Education Teaching Advantage (NETA) program delivers research-based instructor resources that promote student engagement and higher-order thinking to enable the success of Canadian students and educators. Be sure to visit Nelson Education's **Inspired Instruction** website at <http://www.nelson.com/inspired/> to find out more about NETA. Don't miss the testimonials of instructors who have used NETA supplements and seen student engagement increase!

Instructor Resources

Downloadable instructor supplements

All NETA and other key instructor ancillaries can be accessed through www.nelson.com/instructor, giving instructors the ultimate tools for customizing lectures and presentations.

NETA Test Bank: This resource was written by Dr. Alice Khin, University of Alberta. It includes over 5000 questions; 1750 questions are multiple-choice questions written according to NETA guidelines for effective construction and development of higher-order questions. The Test Bank was copy-edited by a NETA-trained editor. Also included are fill in the blank, matching, and true-or-false test items as well as essay questions. The NETA Test Bank is available in a new, cloud-based platform. **Nelson Testing Powered by Cognero**® is a secure online testing system that allows you to author, edit, and manage test bank content from any place you have Internet access. No special installations or downloads are needed, and the desktop-inspired interface, with its drop-down menus and familiar, intuitive tools, allows you to create and manage tests with ease. You can create multiple test versions in an instant, and import or export content into other systems. Tests can be delivered from your learning management system, your classroom, or wherever you want. Nelson Testing Powered by Cognero® for *Human Physiology: From Cells to Systems*, Fourth Canadian Edition, also be accessed through www.nelson.com/instructor. Printable versions of the Test Bank in Microsoft® Word® and PDF formats are available by contacting your sales and editorial representative.

NETA PowerPoint: Microsoft® PowerPoint® lecture slides for every chapter have been created by Dr. Stephen Donald Turnbull, University of New Brunswick. There is an average of 100 slides per chapter, many featuring key figures, tables, and photographs from *Human Physiology: From Cells to Systems*, Fourth Canadian Edition. Incorporating animations and “build slides,” these illustrations with labels from the book have been formatted to allow optimal display in PowerPoint®. NETA principles of clear design and engaging content have been incorporated throughout, making it simple for instructors to customize the deck for their courses.

Image Library: This resource consists of over 600 digital copies of figures, short tables, and photographs used in the book. Instructors may use these JPEG to customize the NETA PowerPoint or create their own PowerPoint presentations.

NETA Instructor's Manual: This resource was written by Dr. Coral Murrant, University of Guelph. It is organized according to the textbook chapters and addresses key educational concerns, such as typical stumbling blocks student face and how to address them. It also includes elements of a traditional Instructor's Manual, including lecture outlines, discussion topics, student activities, Internet connections, media resources, and testing suggestions that will help time-pressed instructors more effectively communicate with their students and also strengthen the coverage of course material.

DayOne: DayOne—Prof InClass is a PowerPoint presentation that instructors can customize to orient students to the class and their text at the beginning of the course.

MindTap

MindTap for Human Physiology: From Cells to Systems, Fourth Canadian Edition, is a personalized teaching experience with relevant assignments that guide students to analyze, apply, and elevate thinking, allowing instructors to measure skills and promote better outcomes with ease. A fully online learning solution, MindTap combines all student learning tools—readings, multimedia, activities, and assessments—into a single Learning Path that guides the student through the curriculum. Instructors personalize the experience by customizing the presentation of these learning tools to their students, even seamlessly introducing their own content into the Learning Path.

Aplia

Aplia™ is a Cengage Learning online homework system dedicated to improving learning by increasing student effort and engagement. Aplia makes it easy for instructors to assign frequent online homework assignments. Aplia provides students with prompt and detailed feedback to help them learn as they work through the questions, and features interactive tutorials to fully engage them in learning course concepts. Automatic grading and powerful assessment tools give instructors real-time reports of student progress, participation, and performance, and while Aplia's easy-to-use course management features let instructors flexibly administer course announcements and materials online. With Aplia, students will show up to class fully engaged and prepared, and instructors will have more time to do what they do best... teach.

Jacqueline Carnegie of the University of Ottawa revised the MindTap and Aplia resources to ensure close alignment to the fourth Canadian edition.

Student Ancillaries

MindTap

Stay organized and efficient with **MindTap**—a single destination with all the course material and study aids you need to succeed. Built-in apps leverage social media and the latest learning technology. For example,

ReadSpeaker will read the text to you.

Flashcards are pre-populated to provide you with a jump start for review—or you can create your own. You can highlight text and make notes in your MindTap Reader. Your notes will flow into Evernote, the electronic notebook app that you can access anywhere when it's time to study for the exam.

Self-quizzing allows you to assess your understanding.

Visit www.nelson.com/student to start using **MindTap**. Enter the Online Access Code from the card included with your text. If a code card is *not* provided, you can purchase instant access at NELSONbrain.com.

Aplia

Founded in 2000 by economist and Stanford professor Paul Romer, **Aplia™** is an educational technology company dedicated to improving learning by increasing student effort and engagement. Currently, Aplia products have been used by more than a million students at over 1300 institutions. Aplia offers a way for you to stay on top of your coursework with regularly scheduled homework assignments that increase your time on task and give you prompt feedback. Interactive tools and additional content are provided to further increase your engagement and understanding. See <http://www.aplia.com> for more information. If Aplia isn't bundled with your copy of *Human Physiology: From Cells to Systems*, Fourth Canadian Edition, you can purchase access separately at NELSONbrain.com. Be better prepared for class with Aplia!

U.S. Acknowledgments

I gratefully acknowledge the many people who helped with the first eight editions or this edition of the textbook. Also, I remain indebted to four people who contributed substantially to the original content of the book: Rachel Yeater (West Virginia University), who contributed the original material for the exercise physiology boxes; Spencer Seager (Weber State University), who prepared Appendix A, “A Review of Chemical Principles”; and Kim Cooper (Midwestern University) and John Nagy (Scottsdale Community College), who provided the Solving Quantitative Exercises at the ends of chapters.

In addition to the 184 reviewers who carefully evaluated the forerunner books for accuracy, clarity, and relevance, I express sincere appreciation to the following individuals who served as reviewers for this edition:

Ahmed Al-Assal, West Coast University

Amy Banes-Berceli, Oakland University

Patricia Clark, Indiana University-Purdue University

Elizabeth Co, Boston University

Steve Henderson, Chico State University

James Herman, Texas A&M University

Qingsheng Li, University of Nebraska-Lincoln

Douglas McHugh, Quinnipiac University

Linda Ogren, University of California, Santa Cruz

Roy Silcox, Brigham Young University

Also, I am grateful to the users of the textbook who have taken time to send helpful comments.

I have been fortunate to work with a highly competent, dedicated team from Cengage Learning, along with other capable external suppliers selected by the publishing company. I would like to acknowledge all of their contributions, which collectively made this book possible. It has been a source of comfort and inspiration to know that so many people have been working diligently in so many ways to bring this book to fruition.

From Cengage Learning, Yolanda Cossio, Senior Product Team Manager, deserves warm thanks for her vision, creative ideas, leadership, and ongoing helpfulness. Yolanda was a strong advocate for making this the best edition yet. Yolanda's decisions were guided by what is best for the instructors and students who will use the textbook and ancillary package. Thanks also to Product Assistant Victor Luu, who coordinated many tasks for Yolanda during the development process.

I appreciate the efforts of Content Developer Alexis Glubka for helping us launch this project and for Managing Developer Trudy Brown for taking over and not missing a beat when Alexis moved to another position. Trudy facilitated most of the development process, which proceeded efficiently and on schedule. Having served as a Production Editor in the past, Trudy was especially helpful in paving the way for a smooth transition from development to production. I am grateful for the biweekly conference calls with Yolanda and Trudy. Their input, expertise, and support were invaluable as collectively we made decisions to make this the best edition yet.

I appreciate the creative insight of Cengage Learning Senior Art Director John Walker, who oversaw the overall artistic design of the text and found the dynamic cover image that displays simultaneous power, agility, and grace in a "body in motion," the theme of our covers. The upward and "over-the-hump" movement of the high jumper symbolizes that this book will move the readers upward and over the hump in their understanding of physiology. I thank John for his patience and perseverance as we sifted through and rejected many photos until we found just what we were looking for.

The technology-enhanced learning tools in the media package were updated under the guidance of Media Developer Lauren Oliveira. These include the online interactive tutorials, media exercises, and other e-Physiology learning opportunities at the CengageBrain website. Associate Content Developers Casey Lozier and Kellie Petruzzelli oversaw development of the multiple hard-copy components of the ancillary package, making sure it was a cohesive whole. A hearty note of gratitude is extended to all of them for the high-quality multimedia package that accompanies this edition.

On the production side, I would like to thank Senior Content Project Manager Tanya Nigh, who closely monitored every step of the production process while simultaneously overseeing the complex production process of multiple books. I felt confident knowing that she was making sure that everything was going according to plan. I also thank Photo Researcher Priya Subbrayal and Text Researcher Kavitha Balasundaram for tracking down photos and permissions for the art and other copyrighted materials incorporated in the text, an absolutely essential task. With everything finally coming together, Manufacturing Planner Karen Hunt oversaw the manufacturing process, coordinating the actual printing of the book.

No matter how well a book is conceived, produced, and printed, it would not reach its full potential as an educational tool without being efficiently and effectively marketed. Senior Market Development Manager Julie Schuster played the lead role in marketing this text, for which I am most appreciative.

Cengage Learning also did an outstanding job in selecting highly skilled vendors to carry out particular production tasks. First and foremost, it has been my personal and professional pleasure to work with Cassie Carey, Production Editor at Graphic World, who coordinated the day-to-day management of production. In her competent hands lay the responsibility of seeing that all copyediting, art, typesetting, page layout, and other related details got done right and in a timely fashion. Thanks to her, the production process went smoothly, the best ever. I also want to extend a hearty note of gratitude to compositor Graphic World for their accurate typesetting; execution of many of the art revisions; and attractive, logical layout. Lisa Buckley deserves thanks for the fresh and attractive, yet space-conscious, appearance of the book's interior and for envisioning the book's visually appealing exterior.

Finally, my love and gratitude go to my family for the sacrifices in family life as this ninth edition was being developed and produced. The schedule for this book was especially hectic because it came at a time when a lot else was going on in our lives. My husband, Peter Marshall, deserves special appreciation and recognition for assuming extra responsibilities while I was working on the book. I could not have done this, or any of the preceding books, without his help, support, and encouragement.

Thanks to all!

Lauralee Sherwood

Canadian Acknowledgments

I am extremely thankful to all the reviewers who took part in the process of developing the fourth Canadian edition of *Human Physiology: From Cells to Systems*. Without your help the text would not be as thorough.

Gary V. Allen	Dalhousie University
Darren S. DeLorey	University of Alberta
Iain McKinnell	Carleton University
Coral Murrant	University of Guelph
Kirsten Poling	University of Windsor
Ramona Stewart	Lethbridge College
Anita Woods	Western University

Reviewers

We would like to thank Nelson, and in particular Paul Fam and Theresa Fitzgerald, for making this project possible and enjoyable. We would also like to thank Imoinda Romain, Carolyn Jongeward, Kim Carruthers, and Udhaya Harisudan for their help in the success of this text. And to all of my colleagues and students, who contributed in many different ways, thanks so much.

Christopher Ward

About the Authors

Lauralee Sherwood, Ph.D. Following graduation from Michigan State University in 1966, Dr. Lauralee Sherwood joined the faculty at West Virginia University, where she is currently a professor in the Department of Physiology and Pharmacology, School of Medicine. For the past 40 years, Professor Sherwood has taught an average of over 400 students each year in physiology courses for pharmacy, medical technology, physical therapy, occupational therapy, nursing, medical, dental, dental hygiene, nutrition, exercise physiology, and athletic training majors. She has authored three physiology textbooks: *Human Physiology: From Cells to Systems*, *Fundamentals of Human Physiology*, and *Animal Physiology: From Genes to Organisms*, all published by Cengage Brooks/Cole. Dr. Sherwood has received numerous teaching awards, including an Amoco Foundation Outstanding Teacher Award, a Golden Key National Honor Society Outstanding Faculty Award, two listings in *Who's Who among America's Teachers*, and the Dean's Award of Excellence in Education.

Christopher Ward, Ph.D. Dr. Ward is an associate professor in the Department of Biomedical and Molecular Sciences at Queen's University. Dr. Ward has taken a leadership role in the

development of innovative teaching methodologies to enhance undergraduate, graduate, and medical student learning. He is credited with the launch of online courses and blended learning initiatives, and is part of a curricular redesign team responsible for pioneering facilitated small-group learning at Queen's Faculty of Medicine. A cardiac physiologist, Dr. Ward also maintains an active laboratory and graduate research team that focuses on studying the electrical activity of the heart and understanding how ion channel function can be modulated by disease states.

About the Contributor (Chapter 14, Fluid and Acid–Base Balance)

Joseph Smuczek, M.D. Dr. Smuczek completed his medical training and postgraduate family medicine training at McMaster University. He is currently a practising physician with the division of Primary Care at Trillium Health Partners in Mississauga, Ontario. He has been actively involved in undergraduate education and medical education and has previously taught undergraduate-level human anatomy and human physiology at Brock University and University of Guelph-Humber.

Homeostasis Systems and Cells

Body systems maintain homeostasis

Da Vinci's Vitruvian Man

Cells make up body systems

Homeostasis

Homeostasis is the maintenance by the highly coordinated, regulated actions of the body systems of relatively stable chemical and physical conditions in the internal fluid environment that bathes the body's cells.

Homeostasis is essential for survival of cells

The Foundation of Physiology

CONTENTS AT A GLANCE

- 1.1 Introduction to physiology
- 1.2 Levels of organization in the body
- 1.3 Concepts of homeostasis
- 1.4 Homeostatic control systems

1.1 Introduction to Physiology

The human body is incredibly complex in that it is made up of a multitude of single cells that come together to form tissues and organ systems. These cells and systems depend on many daily processes that occur in our body to keep us alive. We usually take these life-sustaining activities for granted and don't really think about what makes us tick, but that's what physiology is about. Specifically, in this textbook we will study **human physiology**, the scientific study of the functions of our body.

We will also discuss other disciplines that rely on understanding human physiology, such as **nursing**, **medicine**, and **physical therapy**, to name but a few. In special topic boxes called Concepts, Challenges, and Controversies we address information related to human physiology that you may find interesting. As you read through this chapter and others, you will find another special topic box called Why It Matters, which conveys the importance and relevance of material covered in the chapter. New to this edition is a Clinical Connection feature that presents a clinical case at the beginning of the chapter and then revisits it throughout the chapter to highlight the relevant physiology. To bring it all together, you will also find Check Your Understanding sections that let you pause and see if you have understood the topic so far.

Approaches to understanding

Two approaches are used to explain the events that occur in the body: one emphasizes the purpose, and the other examines the underlying mechanism. In response to the question, “Why do I shiver when I am cold?” one answer would be “to help warm up, because shivering generates heat.” This approach—a **teleological approach**—explains body functions in terms of meeting a bodily need, without considering how this outcome is accomplished; it emphasizes the “why” or purpose of body processes. **Physiologists** (persons who study physiology; see ■ Table 1-1 for a list of Canadian scientists who have received the Nobel Prize for Physiology or Medicine) primarily use a **mechanistic approach** to body function. They view the body as a machine whose mechanisms of action can be explained in terms of cause-and-effect sequences of physical and chemical processes—the same types of processes that occur in other components of the universe. Physiologists therefore explain the “how” of events that occur in the body. A physiologist’s mechanistic explanation of shivering is that when temperature-sensitive nerve cells detect a fall in body temperature, they signal the temperature-sensitive area of the brain. In response, the brain activates nerve pathways that ultimately bring about involuntary, oscillating contraction-relaxation of skeletal muscle (shivering).

Because most bodily mechanisms do serve a useful purpose (naturally selected throughout evolution), it is helpful when studying physiology to predict what mechanistic process would be useful to the body under a particular circumstance. Thus, you can apply a certain amount of logical reasoning to each new situation you encounter in your study of physiology. *If you try to find the thread of logic in what you are studying, you can avoid a good deal of pure memorization, and, more importantly, you will better understand and assimilate the concepts being presented.*

Structure and function

Physiology is closely related to **anatomy**, the study of the structure of the body. Physiological mechanisms are made possible by the structural design and relationships of the various body

■ **TABLE 1-1** Canadians Who Have Received Nobel Prizes in Physiology or Medicine

Year	Name	Discovery Awarded
1923	Frederick Banting	Insulin
1966	Charles B. Huggins	How hormones control the spread of some cancers
1981	David H. Hubel	Information processing in the visual system

2011	Ralph Steinman	The dendritic cell and its role in adaptive immunity

parts that carry out each of these functions. Just as the functioning of an automobile depends on the shapes, organization, and interactions of its various parts, the structure and function of the human body are inseparable. Therefore, as we explain how the body works, we will provide sufficient anatomic background for you to understand the function of the body part under discussion.

Some of the structure–function relationships are obvious. For example, the heart is well designed to receive and pump blood, the teeth to tear and grind food, and the hinge-like elbow joint to permit bending of the elbow. Other situations in which form and function are interdependent are more subtle but equally important. Consider the interface between the air and blood in the lungs: the respiratory airways that carry air from the outside into the lungs branch extensively when they reach the lungs. Tiny air sacs cluster at the ends of the huge number of airway branches. The branching is so extensive that the lungs contain about 300 million air sacs. Similarly, the blood vessels carrying blood into the lungs branch extensively and form dense networks of small vessels that encircle each of the air sacs (see Figure 12-2). Because of this structural relationship, the total surface area exposed to the air in the air sacs and the blood in the small vessels is much larger than a tennis court, depending on the size of the person. This large interface is crucial for the lung’s ability to efficiently carry out the transfer of needed oxygen from the air into the blood and the unloading of the by-product of cellular respiration (carbon dioxide) from the blood into the air. The greater the available surface area for exchange, the faster the rate of movement (i.e., diffusion) of oxygen and carbon dioxide between the air and the blood. This large functional interface packaged within the confines of your lungs is possible only because both the air-containing and blood-containing components of the lungs branch extensively.

1.2 Levels of Organization in the Body

We now turn our attention to how the body is structurally organized into a total functional unit, from the chemical level to the systems level to the whole body (► Figure 1-1). These levels of organization make life as we know it possible.

Chemical level

Like all matter on this planet, the human body is made up of a combination of specific chemicals. *Atoms* are the smallest building blocks of all nonliving and living matter. The most common atoms (or constituents) in the body—oxygen, carbon, hydrogen, and nitrogen—make up approximately 99 percent of total body chemistry. Calcium, phosphorus, and potassium contribute roughly 1 percent. These atoms combine to form the *molecules* of life, such as proteins, carbohydrates, fats, and nucleic acids (genetic material, such as deoxyribonucleic acid, or DNA). These important atoms and molecules are the raw ingredients

FIGURE 1-1 Levels of organization in the body

from which all living things arise. (See Appendix B for a review of this chemical level.)

Cellular level

The mere presence of a particular collection of atoms and molecules does not confer the unique characteristics of life. Instead, these nonliving chemical components must be arranged and packaged in very precise ways to form a living entity. The **cell**, the basic or fundamental unit of both structure and function in a living being, is the smallest unit capable of carrying out the processes associated with life. Cell physiology is the focus of Chapter 2.

An extremely thin, oily barrier, the **plasma membrane**, encloses the contents of each cell, separating these chemicals from those outside the cell. Because the plasma membrane can control the movement of materials into and out of the cell, the cell's interior contains a combination of atoms and molecules that differs from the mixture of chemicals in the exterior environment surrounding the cell. Given the importance of the plasma membrane and its associated functions for carrying out life processes, Chapter 2 describes this structure in detail.

Organisms are independent living entities. The simplest forms of independent life are single-celled organisms, such

as bacteria and amoebas. Complex multicellular organisms, such as trees and humans, are structural and functional aggregates of trillions of cells (*multi* means “many”). In multicellular organisms, cells are the living building blocks. In the simpler multicellular forms of life—for example, a sponge—the cells of the organism are all similar. However, more complex organisms, such as humans, have many different kinds of cells, such as muscle cells, nerve cells, and glandular cells.

Each human organism begins when an egg and sperm unite to form a single cell that starts to multiply and form a growing mass through myriad cell divisions. If cell multiplication were the only process involved in development, all the body cells would be essentially identical, as in the simplest multicellular life forms. During development of complex multicellular organisms, such as humans, however, each cell *differentiates*—that is, becomes specialized to carry out a particular function. Because of **cell differentiation**, your body is made up of many different specialized types of cells.

BASIC CELL FUNCTIONS

All cells, whether they exist as solitary cells or as part of a multicellular organism, perform certain basic functions essential for survival of the cell. These basic cell functions can be described

as metabolism, growth, and reproduction, and include the following:

1. Obtaining food (nutrients) and oxygen (O_2) from the environment surrounding the cell
2. Performing chemical reactions that use nutrients and O_2 to provide energy for the cells, as follows:

3. Eliminating from the cell's internal environment carbon dioxide (CO_2) and other by-products, or wastes, produced during these chemical reactions
4. Synthesizing proteins and other components needed for cell structure, growth, and carrying out particular cell functions
5. Controlling to a large extent the exchange of materials between the cell and its surrounding environment
6. Moving materials from one part of the cell to another when carrying out cell activities. Some cells are even able to move through their surrounding environment
7. Being sensitive and responsive to changes in the surrounding environment
8. For most cells, reproducing. Some body cells, notably nerve cells and cardiac muscle cells, lose the ability to reproduce after they are formed during early development. This is why strokes, which result in losing nerve cells in the brain, and heart attacks, which kill heart muscle cells, can be so devastating.

Cells are remarkably similar in the ways they carry out these basic functions. Thus, they share many common characteristics.

SPECIALIZED CELL FUNCTIONS

In multicellular organisms, each cell also performs a specialized function, which is usually a modification or elaboration of a basic cell function. Here are a few examples:

- The glandular cells of the digestive system take advantage of their protein-synthesizing ability and produce and secrete digestive enzymes (proteins) that break down ingested food.
- The specialized ability of the kidney cells enables them to control the exchange of materials between the cell and its environment to selectively retain needed substances while eliminating unwanted substances in the urine.
- Muscle contraction selectively moves internal structures to bring about the shortening of muscle cells, which shows the inherent capability of these cells to produce intracellular (within the cell) movement; this allows the organism to move through the external environment.
- Nerve cells generate, transmit, and store information in the form of changes in electrical impulse. For example, nerve cells in the ear relay information to the brain about sound in the external environment.

Each cell performs these specialized activities in addition to carrying on the unceasing, fundamental activities required of

all cells. The basic cellular functions are essential to the survival of each individual cell, whereas the specialized contributions and interactions among the cells of a multicellular organism are essential to the survival of the whole body.

Tissue level

Just as a machine does not function unless all its parts are properly assembled, the body's cells must be specifically organized to carry out their life-sustaining processes as a whole, such as digestion, respiration, and circulation. Cells are progressively organized into tissues, organs, body systems, and, finally, the whole body.

Cells of similar structure and specialized function combine to form **tissues**, of which there are four primary types: muscle, nervous, epithelial, and connective. Each tissue consists of cells of a single specialized type, along with varying amounts of extra-cellular (outside the cell) material.

- **Muscle tissue** consists of cells specialized for contracting and generating force. There are three types of muscle tissue: *skeletal muscle*, which moves the skeleton; *cardiac muscle*, which pumps blood out of the heart; and *smooth muscle*, which encloses and controls movement of contents through hollow tubes and organs (e.g., food through the digestive tract).
- **Nervous tissue** consists of cells specialized for initiating and transmitting electrical impulses, which carry information over various distances: for example, one body part to another. Nervous tissue is found in the brain, spinal cord, and peripheral nerves.
- **Epithelial tissue** consists of cells specializing in exchange of materials between the cell and its environment. Any substance entering or leaving the body must cross an epithelial barrier. Epithelial tissue is organized into two general types: epithelial sheets and secretory glands.
 - Epithelial cells join tightly to form sheets of tissue that cover and line various parts of the body; for example, the outer layer of the skin is epithelial tissue, as is the lining of the digestive tract. Generally, these sheets serve as boundaries that separate the body from the external environment and from the contents of cavities that open to the external environment, such as the digestive tract lumen. (A **lumen** is the cavity within a hollow organ or tube.) Only selective transfer of materials is possible between regions separated by an epithelial sheet. The type and extent of controlled exchange vary, depending on the location and function of the epithelial tissue. For example, the skin can exchange very little between the body and external environment, whereas the epithelial cells lining the digestive tract are specialized for absorbing nutrients.
 - **Glands** are epithelial tissue derivatives specialized for secreting. **Secretion** is the release from a cell, in response to appropriate stimulation, of specific products that have been produced by the cell. Glands are formed during embryonic development by pockets of epithelial

tissue that dip inward from the surface and develop secretory capabilities. There are two categories of glands: *exocrine* and *endocrine* (► Figure 1-2). If, during development, the connecting cells between the epithelial surface cells and the secretory gland cells within the depths of the invagination remain intact, as in a duct between the gland and the surface, an exocrine gland is formed. **Exocrine glands** secrete through ducts to the outside of the body (or into a cavity that communicates with the outside) (*exo* means “external”; *crine* means “secretion”). Sweat glands and glands that secrete digestive juices are examples of exocrine glands. In contrast, if the connecting cells disappear during development and the secretory gland cells are isolated from the surface, an endocrine gland is formed. **Endocrine glands** lack ducts and release their secretory products, known as *hormones*, internally into the blood (*endo* means “internal”); for example, the pancreas secretes insulin into the blood, which transports the hormone to its sites of action (e.g., muscle).

- **Connective tissue** is distinguished by having relatively few cells dispersed within an abundance of extracellular material. Connective tissue connects, supports, and anchors body parts. It includes diverse structures such as loose connective tissue that attaches epithelial tissue to underlying structures; tendons, which attach skeletal muscles to bones; bone, which gives the body shape, support, and protection; and blood, which transports materials (e.g., hormones, O_2) from one part of the body to another. Except for blood, the cells within connective tissue produce specific structural molecules that they release into the extracellular spaces between the cells. One such molecule is the rubber-band-like protein fibre *elastin*, whose presence facilitates the stretching and recoiling of structures such as the lungs, which inflate and deflate during breathing.

Muscle, nervous, epithelial, and connective tissue are the primary tissues in a classical sense, as each is an integrated collection of cells of the same specialized structure and function. The term *tissue* is also often used, as in clinical medicine, to mean the aggregate of various cellular and extracellular components that make up a particular organ (e.g., lung tissue or liver tissue).

Organ level

Organs consist of two or more types of primary tissue organized together to perform a particular function or functions. The stomach is an example of an organ made up of all four primary tissue types. The tissues that make up the stomach function collectively to store ingested food, move it forward into the rest of the digestive tract, and begin the digestion of protein. The stomach is lined with epithelial tissue that restricts the transfer of harsh digestive chemicals and undigested food from the stomach lumen into the blood. Epithelial gland cells in the stomach include exocrine cells, which secrete protein-digesting juices into the lumen, and endocrine cells, which secrete a hormone that regulates the stomach’s exocrine secretion and muscle

► **FIGURE 1-2 Exocrine and endocrine gland formation.** (a) Glands arise during development from the formation of pocket-like invaginations of surface epithelial cells. (b) If the cells at the deepest part of the invagination become secretory and release their product through the connecting duct to the surface, an exocrine gland is formed. (c) If the connecting cells are lost and the deepest secretory cells release their product into the blood, an endocrine gland is formed.

contraction. The wall of the stomach contains smooth muscle tissue, whose contractions mix ingested food with the digestive juices and push the mixture out of the stomach and into the intestine. The stomach wall also contains nervous tissue, which, along with hormones, controls muscle contraction and gland secretion. Connective tissue binds together all of these various tissues.

Body system level

Groups of organs are further organized into **body systems**. Each system is a collection of organs that perform related functions and interact to accomplish a common activity essential for

survival of the whole body. For example, the digestive system consists of the mouth, salivary glands, pharynx (throat), esophagus, stomach, pancreas, liver, gallbladder, small intestine, and large intestine. These digestive organs cooperate to break food down into small nutrient molecules that can be absorbed into the blood for distribution to all cells.

The human body has 11 systems: circulatory, digestive, respiratory, urinary, skeletal, muscular, integumentary, immune, nervous, endocrine, and reproductive (► Figure 1-3). Chapters 3 through 17 cover the details of these systems.

Organism level

Each body system depends on the proper functioning of other systems to carry out its specific responsibilities. The whole body of a multicellular organism—a single, independently living individual—consists of the various body systems structurally and functionally linked as an entity that is separate from the external (outside the body) environment. Thus, the body is made up of living cells organized into life-sustaining systems.

The different body systems do not act in isolation from one another. Many complex body processes depend on the interplay among multiple systems. For example, regulation of blood pressure depends on coordinated responses among the cardiac, circulatory, urinary, nervous, and endocrine systems, as you will

learn later. Even though physiologists may examine body functions at any level, from cells to systems (as the title of this book makes clear), their ultimate goal is to integrate these mechanisms into the big picture: how the entire organism works as a cohesive whole.

Currently, researchers are pursuing several approaches for repairing or replacing tissues or organs that can no longer perform vital functions due to disease, trauma, or age-related changes (see Concepts, Challenges, and Controversies). A similar feature in each chapter explores interesting, tangential information on such diverse topics as environmental impact on the body, aging, ethical issues, new discoveries regarding common diseases, historical perspectives, and so on.

Check Your Understanding 1.1

1. Define *physiology*.
2. List and describe the levels of organization in the body.
3. Compare basic cell functions and specialized cell functions.
4. Distinguish among external environment, internal environment, intracellular fluid, extracellular fluid, plasma, and interstitial fluid.

Integumentary system
skin, hair, nails

Immune system
lymph nodes, thymus, bone marrow, tonsils, adenoids, spleen, appendix, white blood cells (not shown), and mucosa-associated lymphoid tissue

Nervous system
brain, spinal cord, peripheral nerves, special sense organs (not shown)

Endocrine system
all hormone-secreting tissues, including hypothalamus, pituitary, thyroid, adrenals, endocrine pancreas, gonads, kidneys, pineal, thymus, and, not shown, parathyroids, intestine, heart, skin, and adipose tissue

Reproductive system
Male: testes, penis, prostate gland, seminal vesicles, bulbourethral glands, and associated ducts
Female: ovaries, oviducts, uterus, vagina, breasts

1.3 Concepts of Homeostasis

Homeostasis

Homeostasis (homeostatic) is the ability of a cell or organism to regulate its internal conditions (e.g., pH), typically using feedback systems (e.g., negative feedback) to minimize variation and maintain health regardless of changes in the external environment (e.g., cold temperatures). Accordingly, if the internal environment changes in some fashion, then purposeful adjustments will be initiated to move the internal environment back toward the point prior to the change. That is, if internal body temperature were to decrease, the body would enact processes (e.g., shivering) to increase internal body temperature to 37°C . *It should be noted that in many cases our body does not have a specific set point (e.g., 37°C) but more a physiological range (e.g., $36\text{--}37^{\circ}\text{C}$) that the body operates most efficiently within (steady state).* Examples addressing homeostasis are often more easily portrayed using a specified set point. However, it should be understood that physiological ranges are more accurate targets for homeostatic mechanisms than one specific value.

Each cell has basic survival skills, but why can't the body's cells live without performing specialized tasks and being organized according to specialization into systems that accomplish the functions essential for the whole body's survival? The cells in a

multicellular organism cannot live without contributions from the other body cells because the vast majority of cells are not in direct contact with the external environment. A single-celled amoeba can directly obtain nutrients and oxygen from, and eliminate waste into, its immediate external surroundings. In contrast, a muscle cell in a multicellular organism needs nutrients and oxygen, yet the muscle cell cannot directly make these exchanges with the environment surrounding the body because the cell is isolated from this external environment. How does the muscle cell make these vital exchanges? The key is the presence of a watery **internal environment** with which the body cells are in direct contact and make life-sustaining exchanges.

Body cells

The fluid collectively contained within all body cells is called **intracellular fluid (ICF)**; the fluid outside the cells is called **extracellular fluid (ECF)** (*intra* means "within"; *extra* means "outside of"). The extracellular fluid is the internal environment of the body, the fluid environment in which the cells live. Note that the internal environment is outside the cells but inside the body. By contrast, the intracellular fluid is inside of each cell, and the external environment is outside the body. You live in the external environment; your cells live within the body's internal environment.

The Science and Direction of Stem Cell Research in Canada

1

What Are Stem Cells?

Stem cells are undifferentiated cells that are found in all multicellular organisms (e.g., humans). These primal cells maintain the ability to renew themselves through cell division (mitosis) and can differentiate into a wide variety of specialized cell types. Human stem cell research grew from the findings of Canadian scientists Ernest McCulloch and James Till in the 1960s. There are two broad categories of mammalian stem cells: *embryonic stem cells*, which are derived from blastocysts; and *adult stem cells*, which are found in adult tissues. In the developing embryo, stem cells are able to differentiate into all of the specialized embryonic tissues. In adults, however, the stem cells and progenitor cells act as a repair system for the body. Because stem cells can be readily grown and transformed through cell culture into specialized cells with characteristics consistent with cells of various tissues, such as muscles or nerves, their use in medical therapies has been proposed. In particular, embryonic cell lines and highly plastic adult stem cells from umbilical cord blood or bone marrow are believed to be promising candidates for use in medical therapy.

Medical Treatments

Researchers believe that stem cell treatments have the potential to change the way we treat human disease. A number of stem cell treatments already exist, although most are still experimental or very controversial. An example of one treatment that is not experimental is bone marrow transplants. Medical researchers predict the use of stem cells to treat spinal cord injuries, cancer, muscle damage, and even degenerative diseases such as Parkinson's and Alzheimer's. Technical difficulties remain, however, and slow the progress of adult stem cell therapeutics. For example, challenges exist in extracting sufficient adult stem cell populations from patients and efficiently growing

enough stem cells to add corrective factors. These and other problems still need to be solved. There also still exists a great deal of social uncertainty surrounding embryonic stem cell research.

Controversy over the Process

In general, the controversy over stem cell research centres on the techniques used in the creation and use of embryonic stem cells. The state of technology today requires the destruction of a human embryo and/or therapeutic cloning in order to establish a human stem cell line. Opponents of stem cell research argue that this practice is very similar to reproductive cloning, which devalues the worth of a potential human being. Proponents of stem cell research argue that the research is necessary because the results are expected to have significant medical potential and the human cost is minimal: the embryos used for stem cell research had been allocated for destruction anyway. The debate has prompted medical and governmental authorities worldwide to develop a regulatory framework that will speak to both social and ethical challenges.

In 2002, the Canadian Institutes for Health Research (CIHR) first developed guidelines governing the use of stem cells for research in Canada (*Human Pluripotent Stem Cell Research: Guidelines for CIHR-Funded Research*). Since then, these guidelines have continued to be updated as this field of scientific research continues to develop. These guidelines are based on six guiding principles:

- Research undertaken should have potential health benefit for all Canadians rather than just specific groups.
- Free and informed consent must be voluntarily provided; this includes consent from donors of both the sperm and the ova used to create embryos, which is highly relevant for those opting for in vitro fertilization if the surplus embryos may be used for research.
- Respect for privacy and confidentiality must be upheld.

The extracellular fluid (internal environment) is made up of two components: **plasma**, the fluid portion of the blood; and **interstitial fluid**, which surrounds and bathes the cells (*inter* means “between”; *stitial* means “that which stands”) (► Figure 1-4).

No matter how remote a cell is from the external environment, it can make life-sustaining exchanges with its own surrounding internal environment. In turn, particular body systems transfer materials between the external environment and the internal environment so that the composition of the internal environment is maintained (e.g., homeostasis; p. 9) to support the life and functioning of the cells. For example, the digestive system transfers the nutrients required by all body cells from the external environment into the plasma. Likewise, the respiratory system transfers oxygen from

the external environment into the plasma. The circulatory system distributes these nutrients and oxygen throughout the body. Materials are thoroughly mixed and exchanged between the plasma and the interstitial fluid across the capillaries, the smallest and thinnest of the blood vessels. As a result, the nutrients and oxygen originally obtained from the external environment are delivered to the interstitial fluid surrounding the cells. The body cells, in turn, pick up these needed supplies from the interstitial fluid. Similarly, wastes produced by the cells are extruded into the interstitial fluid, picked up by the plasma, and transported to the organs that specialize in eliminating these wastes from the internal environment to the external environment. The lungs remove carbon dioxide from the plasma, and the kidneys remove other wastes for elimination in the urine.

- There can be no direct or indirect payment for tissues collected for stem cell research and no financial incentives.
- Embryos cannot be created for research purposes.
- Respect individual and community notions of human dignity and physical, spiritual, and cultural integrity.

In 2014, these guidelines were integrated into the 2nd Edition of the Tri-Council Policy Statement: Ethical Conduct for Research Involving Humans.

The Search for Noncontroversial Stem Cells

In 2007, the Japanese research team led by Shinya Yamanaka announced that they had created pluripotent stem cells using human skin cells. This finding was a major step forward as it meant that researchers were able to obtain pluripotent stem cells for research without the need of embryos. This type of stem cell is what we now call induced pluripotent stem cells (iPSC or iPS). The technique involves using viral vectors to introduce stem cell-associated genes into nonpluripotent cells and then selectively choosing cells that have the characteristics of stem cells. Although this discovery increased the availability of stem cells for research, its therapeutic potential was limited as it was also prone to the formation of cancers.

Canadian Efforts

Canadians have played many prominent roles in stem cell research. As early as 1961, Canadian scientists James Till and Ernest McCulloch were the first to demonstrate the existence of stem cells, for which they were awarded the 2005 Lasker Prize. In 1992, Dr. Sam Weiss, the 2008 Gairdner award-winning scientist at the University of Calgary, identified stem cells in the adult brain and discovered that the brain

uses these stem cells to heal itself. At the University of Toronto in 1994, Derek van der Kooy identified retinal stem cells in mice, while John Dick isolated the first cancer stem cells from a leukemia patient. More recent advances include Andras Nagy's contributions, in collaboration with Scottish scientists, which allows the creation of iPSCs without the use of potentially cancer-causing viral vectors, and the work by Freda Miller's discovery of skin-derived progenitor cells, which are currently being investigated for use in spinal cord injury. These are just a few examples of important research by Canadians.

The **Stem Cell Network (SCN)** is a Canadian venture that fosters ethical stem cell research by bringing together more than 100 individuals to examine the therapeutic potential of stem cells. The network was started by a \$21.1-million grant from the Networks of Centres of Excellence in 2001. It includes scientists, clinicians, engineers, and ethicists. Funding is made possible by the Natural Sciences and Engineering Research Council of Canada (NSERC), Canadian Institutes of Health Research (CIHR), and the Social Sciences and Humanities Research Council (SSHRC), in partnership with Industry Canada. The goal of SCN is "to be a catalyst for realizing the full potential of stem cell research for Canadians." More information about SCN can be found at <http://www.stemcellnetwork.ca>. Diseases that may benefit from stem cell research include cancer, HIV/AIDS, diabetes, and obesity.

Body systems

The body cells can live and function only when the extracellular fluid is compatible with their survival; thus, the chemical composition and physical state of this internal environment must be maintained within narrow limits, that is, a physiological range (e.g., pH). As cells take up nutrients and oxygen from the internal environment, these essential materials are continuously replenished. Similarly, wastes are constantly removed from the internal environment so that they do not reach toxic levels. Other aspects of the internal environment important for maintaining life, such as temperature and pH, must be kept relatively constant.

The functions performed by each body system contribute to homeostasis, thereby maintaining our internal environment

and making survival of all the cells possible. Cells, in turn, make up body systems. This theme is central to physiology and this book: *Homeostasis is essential for the survival of each cell, and each cell, through its specialized activities, contributes as part of a body system to the maintenance of the internal environment shared by all cells* (► Figure 1-5).

Homeostasis is not a rigid, fixed state, or absolute setting, but rather a dynamic, steady state in which changes occur but are minimized by multiple dynamic equilibrium adjustment mechanisms (basic component parts are receptor, control centre, effector). Both external and internal factors continuously activate these adjustment mechanisms to maintain a relatively stable internal environment. The term *dynamic* refers to the fact that each homeostatically regulated factor is marked

► **FIGURE 1-4** Components of the extracellular fluid (internal environment).

A body cell takes in essential nutrients from its watery surroundings and eliminates wastes into these same surroundings, just as an amoeba does. The main difference is that each body cell must help maintain the composition of the internal environment so that this fluid continuously remains suitable to support the existence of all the body cells. In contrast, an amoeba does nothing to regulate its surroundings.

by continuous change, whereas *steady state* implies that these changes do not deviate too far from a constant level. This situation is comparable to the minor steering adjustments made while driving a car along a straight course down the highway. Small fluctuations around the optimal level for each factor in the internal environment are normally kept, by carefully regulated mechanisms, within the narrow limits of a physiological range compatible with life.

Some of the dynamic equilibrium adjustments are immediate, transient responses to a situation that moves a regulated factor in the internal environment outside the desired range. Others are more long-term (i.e., chronic) adaptations that take place in response to prolonged or repeated exposure to a situation that disrupts homeostasis (e.g., exercise). Chronic adaptations make the body more efficient in responding to an ongoing or repetitive challenge. The body's reaction to exercise includes examples of both short-term (i.e., acute) compensatory responses and chronic adaptations among the different body systems: for example, the acute response of the body to environmental heat.

FACTORS HOMEOSTATICALLY REGULATED

Many factors of the internal environment must be homeostatically maintained, including the following:

1. **Concentration of nutrient molecules.** Cells need a constant supply of nutrient molecules for energy production. Energy, in turn, is needed to support life-sustaining and specialized cell activities.

► **FIGURE 1-5** Interdependent relationship of cells, body systems, and homeostasis. The depicted interdependent relationship serves as the foundation for modern-day physiology: homeostasis is essential for the survival of cells; body systems maintain homeostasis; and cells make up body systems.

2. **Concentration of oxygen and carbon dioxide.** Cells need oxygen to carry out energy-yielding chemical reactions. The carbon dioxide produced during these reactions must be removed so that acid-forming carbon dioxide does not increase the acidity of the internal environment.

3. **Concentration of waste products.** Some chemical reactions produce end products that exert a toxic effect on the body's cells if these wastes are allowed to accumulate.

4. **pH.** Changes in the pH (relative amount of acid) adversely affect nerve cell function and wreak havoc with the enzymatic activity of all cells.

5. **Concentration of water, salt, and other electrolytes.** Because the relative concentrations of salt and water in the extracellular fluid influence how much water enters or leaves the cells, these concentrations are carefully regulated to maintain the proper volume of the cells. Cells do not function normally when they are swollen or shrunk. Other electrolytes perform a variety of vital functions. For example, the rhythmic beating of the heart depends on a relatively constant concentration of potassium in the extracellular fluid.

6. **Volume and pressure.** The circulating component of the internal environment—the plasma—must be maintained at adequate volume and blood pressure to ensure body-wide distribution of this important link between the external environment and the cells.

7. **Temperature.** Body cells function best within a narrow temperature range. If cells are too cold, their functions slow down

too much; worse yet, if they get too hot, their structural and enzymatic proteins are impaired or destroyed.

CONTRIBUTIONS OF THE BODY SYSTEMS TO HOMEOSTASIS

The 11 body systems contribute to homeostasis in the following important ways. (Note that the figure included on the inside front cover can be used as a handy reference to help you keep track of how all the pieces fit together.)

1. The *circulatory system* transports materials, such as nutrients, oxygen, carbon dioxide, wastes, electrolytes, and hormones, from one part of the body to another. It also assists with temperature regulation by moving heat to the periphery from the core.
2. The *digestive system* breaks down dietary food into small nutrient molecules that can be absorbed into the plasma for distribution to the body cells, and transfers water and electrolytes from the external environment into the internal environment. It eliminates undigested food residues to the external environment in the feces.
3. The *respiratory system*, consisting of the lungs and major airways, receives oxygen from the external environment and eliminates carbon dioxide from the internal environment. By adjusting the rate of removal of acid-forming carbon dioxide, the respiratory system is also important in maintaining the proper pH of the internal environment.
4. The *urinary system* removes excess water, salt, acid, and other electrolytes from the plasma and eliminates them in the urine, along with waste products other than carbon dioxide. This system includes the kidneys and associated “plumbing.”
5. The *skeletal system* (bones and joints) provides support and protection for the soft tissues and organs. It also serves as a storage reservoir for calcium, an electrolyte whose plasma concentration must be maintained within very narrow limits. Furthermore, the bone marrow—the soft interior portion of some types of bone—is the ultimate source of all blood cells.
6. The *muscular system* (skeletal muscles) and skeletal system form the basis of movement. The skeletal muscles attach via tendons to bones. When the muscles contract, this enables the bones to move and lets us walk, grab, and jump. From a purely homeostatic view, this system enables an individual to move toward food or away from harm. Furthermore, the heat generated by muscle contraction is important in temperature regulation. In addition, because skeletal muscles are under voluntary control, a person can use them to accomplish many other movements. These movements, which range from the fine motor skills required for delicate needlework to the powerful movements involved in weightlifting, are not necessarily directed toward maintaining homeostasis.
7. The *integumentary system* (skin and related structures) serves as an outer protective barrier that prevents internal

fluid from being lost from the body and foreign microorganisms from entering (part of our external defence; p. 460). This system is also important in regulating body temperature. The amount of heat lost from the body surface to the external environment can be adjusted by controlling sweat production and by regulating the flow of warm blood through the skin.

8. The *immune system* (white blood cells and lymphoid organs) defends against foreign invaders and body cells that have become cancerous. It also paves the way for repairing or replacing injured or worn-out cells.
9. The *nervous system* (brain, spinal cord, and nerves) is one of the two major regulatory systems of the body. In general, it controls and coordinates bodily activities that require swift responses. The nervous system is especially important in detecting and initiating reactions to changes in the external environment. It is also responsible for higher functions that are not entirely directed toward maintaining homeostasis, such as consciousness, memory, and creativity.
10. The *endocrine system* is the other major regulatory system (and a communication system). Unlike the nervous system (our body’s fast communication system), in general the hormone-secreting glands of the endocrine system regulate activities that require duration rather than speed, such as growth. This system is especially important in controlling the concentration of nutrients and, by adjusting kidney function, controlling the internal environment’s volume and electrolyte composition.
11. The *reproductive system* is essential for perpetuating the species. Homeostatic mechanisms ensure that both the male and female reproductive systems are optimized to favour reproductive success.

As we examine each of these systems in greater detail, always keep in mind that the body is a well-coordinated and integrated whole, even though each system provides its own special contributions. It is easy to forget that all the body parts actually fit together into a functioning, interdependent whole body. Accordingly, each chapter begins with a figure and a discussion that focus on how the body system described in that chapter fits into the body as a whole. In addition, each chapter ends with a brief overview of the homeostatic contributions of the body system. You should also be aware that the whole functioning is greater than the sum of its separate parts. Through specialized, coordinated, and interdependent functions, cells combine to form an integrated, unique, single living organism with more diverse and complex capabilities than those possessed by any of the cells that make it up. For humans, these capabilities go far beyond the processes needed to maintain life. A cell, or even a random combination of cells, obviously cannot create an artistic masterpiece or design a spacecraft, but body cells working together permit an individual to create these things.

You have now learned what homeostasis is and how the functions of different body systems maintain it. Now let’s look at the regulatory mechanisms by which the body reacts to changes and controls the internal environment.

1.4 | Homeostatic Control Systems

1

To maintain homeostasis you need a homeostatic control system. This is a functionally interconnected network of body components that operate to maintain a given factor (variable; e.g., temperature) in the internal environment within a narrow range to maintain a steady state. To maintain homeostasis, the control system must be able to (1) detect deviations from normal in the internal environment (receptor), (2) integrate this information with any other relevant information (control centre), and (3) trigger the needed adjustments responsible for restoring this factor within the normal range (effector).

Local or body-wide control

Homeostatic control systems can be grouped into two classes—**intrinsic** and **extrinsic** controls. **Intrinsic (local) controls** are built into or are inherent in an organ (*intrinsic* means “within”). For example, as an exercising skeletal muscle rapidly uses up oxygen to generate energy to support its contractile activity, the oxygen concentration within the muscle falls. This local chemical change acts directly on the smooth muscle in the walls of the blood vessels that supply the exercising muscle, causing the smooth muscle to relax so that the vessels dilate (open wider). As a result, an increased amount of blood flows through the dilated vessels into the exercising muscle, bringing in more oxygen. This local mechanism helps maintain an optimal level of oxygen in the interstitial fluid around the exercising muscle’s cells.

However, most factors in the internal environment are maintained by **extrinsic controls**, which are regulatory mechanisms initiated outside an organ to alter the activity of the organ (*extrinsic* means “outside of”). Extrinsic control of the organs and body systems is achieved by the two major regulatory systems, the nervous and endocrine systems. Extrinsic control permits synchronized regulation of several organs to a common goal; in contrast, intrinsic controls are self-serving for the organ in which they occur. Coordinated regulatory mechanisms are crucial to maintain the dynamic equilibrium associated with the steady state of the internal environment. To maintain blood pressure within the necessary range, the nervous system simultaneously acts on the heart and the blood vessels throughout the body to increase or decrease blood pressure.

To stabilize the necessary physiological factors, homeostatic control systems must be able to detect and make the necessary adjustments to various changes. In making these dynamic equilibrium adjustments, feedback and feedforward loops come into play. The term **feedback** refers to responses made after a change has been detected; the term **feedforward** describes responses made in anticipation of a change. Let’s take a look at these mechanisms in more detail.

Negative feedback

Homeostatic control mechanisms operate primarily on the principle of negative feedback, which attempts to provide stability within the internal environment. In **negative feedback**, a

change in a homeostatically controlled factor triggers a response that seeks to maintain homeostasis by moving the factor in the opposite direction of its initial change. That is, a corrective adjustment opposes the original deviation from the homeostatic steady state.

For example, room temperature is a **controlled variable** (factor) held within a narrow range by a control system. The control system includes a thermostatic device, a furnace, and all their electrical connections. Room temperature is determined by the activity of the furnace. To switch on or switch off the furnace, the control system as a whole must be able to determine what the *actual* room temperature is, compare this with the *desired* room temperature, and adjust the output of the furnace to maintain the temperature in the desired level. A thermometer provides information about the actual room temperature, acting as a **sensor** (physiologically, a sensor is termed a *receptor*) to monitor the magnitude and direction of the controlled variable. The sensor typically converts the information regarding a change into a language the control system can understand. For example, the thermometer part of the thermostat converts the magnitude of the air temperature into electrical impulses. This message serves as the input into the control system. The thermostat setting provides the desired temperature steady state. The thermostat acts as a **control centre** (integrator), which compares the sensor’s input with the optimal range and adjusts the furnace output to bring about the appropriate response, opposing the deviation outside the range, which provides stability. The furnace is the **effector**, the component of the control system that brings about the desired effect. These general components of a negative-feedback control system are summarized in ▶ Figure 1-6a.

Let’s look at a typical negative-feedback loop. When room temperature falls below the predetermined range, the thermostat activates the furnace, which produces heat to raise the room temperature to the selected steady state (▶ Figure 1-6b). Once the room temperature reaches the predetermined range, the thermometer no longer detects a deviation in temperature, and the thermostat no longer activates the furnace. In this way, the heat from the furnace counteracts, or is *negative* to, the original fall in temperature. If the heat-generating pathway were not shut off once the target temperature was reached, heat production would continue indefinitely increasing the temperature. Overshooting the optimal range does not occur, because the heat “feeds back” to shut off the thermostat and terminate the heat output. Thus, a negative-feedback control system detects any change in a controlled factor away from the steady-state value, initiates mechanisms to correct the situation, and then shuts itself off.

What happens when the original deviation involves a rise in room temperature above the selected steady state? A heat-producing furnace is of no use in returning the room temperature to the desired level. In this case, the thermostat activates a different effector, an air conditioner, to cool the room air. The effect is opposite that of the furnace. Using negative feedback, the optimal range is reached, and the air conditioner is turned off to prevent overcooling. However, if the house is equipped with only a furnace that produces heat to oppose a fall in room temperature, no mechanism is available to prevent the house from getting too hot. To keep room temperature at a steady state,

two opposing mechanisms must be used: one that heats and one that cools.

Homeostatic negative-feedback systems in the human body operate in the same way. When temperature-monitoring nerve cells in the hypothalamus detect a decrease in body temperature below the physiological range, they signal other nerve cells in a control centre, which initiate shivering (and other responses) to generate metabolic heat and increase body temperature to within the physiological range (► Figure 1-6c). When body temperature rises to within the physiological range, the temperature-monitoring nerve cells turn off the stimulatory signal to the skeletal muscles, stopping the shivering. Conversely, when the temperature-monitoring nerve cells in the hypothalamus detect a rise in body temperature above normal, cooling mechanisms, such as sweating, come into play to reduce the temperature to normal. When the temperature reaches the physiological range, the cooling mechanisms are shut off. As with body temperature, opposing mechanisms can move most homeostatically controlled variables in either direction as needed.

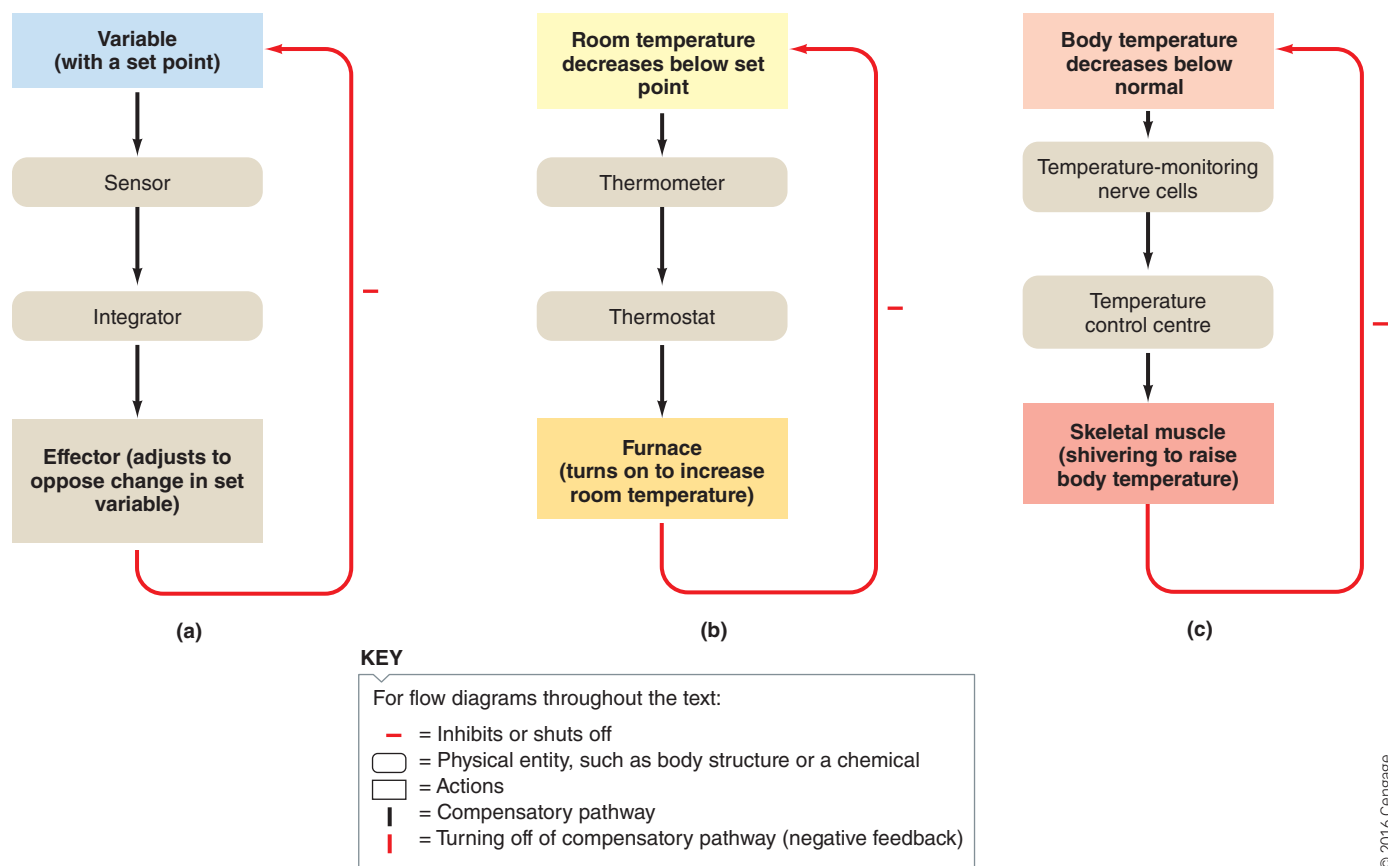

Positive feedback

Negative feedback is used to resist change and add stability to the internal environment. With **positive feedback** the output enhances or amplifies a particular change so that the controlled

factor continues to move in the direction of the initial change. This action is comparable to the heat generated by a furnace triggering the thermostat to call for even *more* heat output from the furnace, increasing room temperature even more.

Because the body's goal is to remain within a relatively stable homeostatic range, positive feedback occurs much less frequently than negative feedback. Positive feedback is used in certain circumstances, such as child birth. The hormone oxytocin causes powerful uterine contractions. These contractions push the baby against the cervix, stretching the cervix. This stretch activates sensors that lead to the release of more oxytocin, which causes stronger uterine contractions, triggering the release of more oxytocin, and so on. This positive-feedback cycle does not stop until the baby exits the cervix. Likewise, all other normal instances of positive feedback include some mechanism for stopping the cycle. However, some abnormal circumstances are characterized by runaway positive-feedback loops that continue to move the body farther and farther from homeostatic balance, potentially until death or a medical intervention stops the cycle.

Such an example of abnormal positive feedback occurs during heatstroke. When temperature-regulating mechanisms are unable to cool the body sufficiently in the face of pronounced environmental heat exposure, the body temperature may rise so high that the temperature control centre becomes impaired. Because

► **FIGURE 1-6 Negative feedback.** (a) Components of a negative-feedback control system. (b) Negative-feedback control of room temperature. (c) Negative-feedback control of body temperature

the temperature control centre is dysfunctional, its ability to start the cooling mechanism is diminished and body temperature continues to increase, causing further damage to the control centre. As a result, body temperature spirals out of control.

Feedforward mechanisms and anticipation

Feedback mechanisms bring about a reaction to a change in a regulated factor, whereas a feedforward mechanism anticipates change in a regulated factor. For example, when a meal is still in the digestive tract, a feedforward mechanism increases secretion of a hormone (insulin) that will promote the cellular uptake and storage of ingested nutrients after they have been absorbed from the digestive tract. This anticipatory response helps limit the rapid rise in nutrients (e.g., glucose) after absorption into the blood, assisting in maintenance of a more steady-state blood nutrient level.

Disruptions in homeostasis

Despite control mechanisms, when one or more of the body's systems malfunction, homeostasis is disrupted, and the regulated factor moves outside the dynamic range in which it most effectively operates. In this situation, all cells suffer because they no longer have an optimal environment in which to live and function. Various pathophysiological states ensue, depending on the type and extent of homeostatic disruption. The term **pathophysiology** refers to the abnormal functioning of the body (altered physiology) associated with disease. The result of disease may be a homeostatic disruption that is so severe that it is no longer compatible with survival, and death results.

Check Your Understanding 1.2

1. Distinguish between intrinsic controls and extrinsic controls.
2. Compare and contrast negative feedback and positive feedback.
3. Draw a diagram of negative feedback showing how the different components are connected.

Chapter in Perspective: Focus on Homeostasis

In this chapter, you have learned what homeostasis is: a dynamic, steady state of the constituents in the internal fluid environment (the extracellular fluid) that surrounds and exchanges materials with the cells. Maintenance of homeostasis is essential for the survival and normal functioning of cells. Each cell, through its specialized activities, contributes as part of a body system to the maintenance of homeostasis.

This relationship is the foundation of physiology and the central theme of this book. We have described how cells are organized according to specialization into body systems. How homeostasis is essential for cell survival and how body systems maintain this internal constancy are the topics covered in the rest of this book. Each chapter concludes with this capstone feature to facilitate your understanding of how the system under discussion contributes to homeostasis, as well as of the interactions and interdependency of the body systems.

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-35)

- Which of the following activities is NOT carried out by every cell in the body?
 - Obtaining oxygen and nutrients
 - Performing chemical reactions to acquire energy for the cell's use
 - Eliminating wastes
 - Controlling to a large extent exchange of materials between the cell and its external environment
 - Reproducing
- What is the proper progression of the levels of organization in the body?
 - Chemicals, cells, organs, tissues, body systems, whole body
 - Chemicals, cells, tissues, organs, body systems, whole body
 - Cells, chemicals, tissues, organs, whole body, body systems
 - Cells, chemicals, organs, tissues, whole body, body systems
 - Chemicals, cells, tissues, body systems, organs, whole body
- Which of the following is NOT a type of connective tissue?
 - Bone
 - Blood
 - The spinal cord
 - Tendons
 - The tissue that attaches epithelial tissue to underlying structures
- The term *tissue* can apply either to one of the four primary tissue types or to a particular organ's aggregate of cellular and extracellular components. (*True or false?*)
- Cells in a multicellular organism have specialized to such an extent that they have little in common with single-celled organisms. (*True or false?*)
- Cell specializations are usually a modification or elaboration of one of the basic cell functions. (*True or false?*)
- The four primary types of tissue are _____, _____, _____, and _____.
- The term _____ refers to the release from a cell, in response to appropriate stimulation, of specific products that have in large part been synthesized by the cell.
- _____ glands secrete through ducts to the outside of the body, whereas _____ glands release their secretory products, known as _____, internally into the blood.
- _____ controls are inherent to an organ, whereas _____ controls are regulatory mechanisms initiated outside an organ that alter the activity of the organ.
- Match the following:

___ 1. circulatory system	(a) obtains oxygen and eliminates carbon dioxide
___ 2. digestive system	(b) support, protect, and move body parts
___ 3. respiratory system	(c) controls, via hormones it secretes, processes that require duration
___ 4. urinary system	(d) acts as transport system
___ 5. muscular and skeletal systems	(e) removes wastes and excess water, salt, and other electrolytes
___ 6. integumentary system	(f) perpetuates the species
___ 7. immune system	(g) obtains nutrients, water, and electrolytes
___ 8. nervous system	(h) defends against foreign invaders and cancer
___ 9. endocrine system	(i) acts through electrical signals to control body's rapid responses
___ 10. reproductive system	(j) serves as outer protective barrier

Written Questions

- Define *physiology*.
- What are the basic cell functions?
- Distinguish between the external environment and the internal environment. What constitutes the internal environment?
- What fluid compartments make up the internal environment?
- Define *homeostasis*.
- Describe the interrelationships among cells, body systems, and homeostasis.
- What factors must be homeostatically maintained?
- Define and describe the components of a homeostatic control system.
- Compare and contrast negative and positive feedback.

POINTS TO PONDER

(Explanations in Appendix E, p. A-35)

1. Considering the nature of negative-feedback control and the function of the respiratory system, what effect do you predict that a decrease in carbon dioxide in the internal environment would have on how rapidly and deeply a person breathes?
2. Would the oxygen levels in the blood be (a) normal, (b) below normal, or (c) elevated in a patient with severe pneumonia resulting in impaired exchange of oxygen and carbon dioxide between the air and blood in the lungs? Would the carbon dioxide levels in the same patient's blood be (a) normal, (b) below normal, or (c) elevated? Because CO_2 reacts with H_2O to form carbonic acid (H_2CO_3), would the patient's blood (a) have a normal pH, (b) be too acidic, or (c) not be acidic enough (i.e., be too alkaline), assuming that other compensatory measures have not yet had time to act?
3. The hormone insulin enhances the transport of glucose (sugar) from the blood into most body cells. Its secretion is controlled by a negative-feedback system between the concentration of glucose in the blood and the insulin-secreting cells. Therefore, which of the following statements is correct?
 - a. A decrease in blood glucose concentration stimulates insulin secretion, which in turn further lowers blood glucose concentration.
 - b. An increase in blood glucose concentration stimulates insulin secretion, which in turn lowers blood glucose concentration.
 - c. A decrease in blood glucose concentration stimulates insulin secretion, which in turn increases blood glucose concentration.
 - d. An increase in blood glucose concentration stimulates insulin secretion, which in turn further increases blood glucose concentration.
4. Given that most AIDS victims die from overwhelming infections or rare types of cancer, what body system do you think HIV (the AIDS virus) impairs?
5. Body temperature is homeostatically regulated around a physiological range. Given your knowledge of negative feedback and homeostatic control systems, predict whether narrowing or widening of the blood vessels of the skin will occur when a person exercises strenuously. (Hint: Muscle contraction generates heat. Narrowing of the vessels supplying an organ decreases blood flow through the organ, whereas vessel widening increases blood flow through the organ. The more warm blood flowing through the skin, the greater the loss of heat from the skin to the surrounding environment.)

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-35)

Jennifer R. has a stomach flu that is going around campus. She has been vomiting profusely for the past 24 hours. Not only has she been unable to keep down fluids or food, but she has also lost the acidic digestive juices secreted by the stomach that are normally

reabsorbed back into the blood farther down the digestive tract. In what ways might this condition threaten to disrupt homeostasis in Jennifer's internal environment? That is, what homeostatically maintained factors are moved away from normal by her profuse vomiting? What body systems respond to resist these changes?

Body Systems

Body systems maintain homeostasis

Electron micrograph of the Golgi apparatus

Cells make up body systems

Cells are the body's living building blocks. Just as the body as a whole is highly organized, so too is a cell's interior. A cell has three major parts: a *plasma membrane* that encloses the cell; the *nucleus*, which houses the cell's genetic material; and the *cytoplasm*, which is organized into discrete, highly specialized *organelles* dispersed throughout a gel-like liquid, the *cytosol*. The cytosol is pervaded by a protein scaffolding, the *cytoskeleton*, that serves as the "bone and muscle" of the cell.

Through the coordinated actions of each of these cell components, every cell can perform certain basic functions essential to its own survival as well as a specialized task that helps maintain homeostasis. Cells are organized according to their specialization into body systems that maintain the stable internal environment essential for the whole body's survival. All body functions ultimately depend on the activities of the individual cells that compose the body.

The same chemicals that make up living cells are also found in nonliving objects. Even though researchers have analyzed the chemicals of which cells are made, they have not been able to organize these chemicals into a living cell in a laboratory. Life stems from the complex organization and interaction of these chemicals within the cell. Groups of inanimate chemicals are structurally organized and function together in unique ways to form a cell, the smallest living entity. Cells, in turn, serve as the living building blocks for the immensely complicated whole body. Thus, cells are the bridge between chemicals and humans (and all living organisms). Furthermore, each new cell and all new life arise from the division of pre-existing cells, not from nonliving sources. Because of this continuity of life, the cells of all organisms are fundamentally similar in structure and function. Table 2-1 summarizes these principles, which are known collectively as the **cell theory**. By probing deeper into the molecular structure and organization of the cells that make up the body, modern physiologists are unravelling many of the broader mysteries of how the body works.

TABLE 2-1 Principles of the Cell Theory

- The cell is the smallest structural and functional unit capable of carrying out life processes.
- The functional activities of each cell depend on the specific structural properties of the cell.
- Cells are the living building blocks of all plant and animal organisms.
- An organism's structure and function ultimately depend on the individual and collective structural characteristics and functional capabilities of its cells.
- All new cells and new life arise only from pre-existing cells.
- Because of this continuity of life, the cells of all organisms are fundamentally similar in structure and function.

2.1 Observation of Cells

Until the invention of the microscope in the middle of the 17th century, scientists did not know that the cell existed. It is not entirely clear who invented the microscope, but three people from the Netherlands are given credit: Hans Lippershey, and Hans and Zacharias Janssen (who were father and son). In the early part of the 19th century, with the development of better light microscopes (the lens quality improved greatly), researchers learned that all plant and animal tissues consist of individual cells. The cells of a hummingbird, a human, and a whale are all about the same size. Larger species have a greater number of cells, not larger cells. These early investigators also discovered that cells are filled with a fluid, which, given the microscopic capabilities of the time, appeared to be a rather uniform, soupy mixture believed to be the elusive “stuff of life.” In the 1940s, when scientists first employed the technique of electron microscopy to observe living matter, they began to understand the great diversity and complexity of the internal structure of cells. Electron microscopes have approximately 1000 times more magnification as light microscopes. Modern microscopic techniques like confocal imaging even allow us to look into live cells. Now that scientists have even more sophisticated microscopes, biochemical techniques, cell culture technology, and genetic engineering, the concept of the cell as a microscopic bag of formless fluid has given way to the current understanding of the cell as a complex, highly organized, compartmentalized structure.

Check Your Understanding 2.1

1. State the principles of the cell theory.
2. Compare the average size of cells in your body with those in a mouse and in an elephant.

2.2 An Overview of Cell Structure

The trillions of cells in a human body are classified into about 200 different cell types based on specific variations in structure and function. Even though there is no such thing as a typical cell, because of these diverse structural and functional specializations, different cells share many common features. For example, a single skeletal muscle cell is cylindrical and elongated, but it can vary in length, which depends on the recruitment of **myoblasts** into existing fibres. A muscle cell in the sartorius muscle of the thigh contains single cells that can be 300 mm (30 centimetres) in length. Every muscle cell contains multiple nuclei (i.e., they are multinucleated), as well as cytosol, ribosomes, and mitochondria, which are common to many cells. Depending on the type of muscle cell (type I or type II; p. 318), there may be differences in the number or volume of mitochondria. A series of common components are also directly associated with force generation and are more specific to the muscle cell. Examples of these components are regulatory proteins (troponin and tropomyosin), contractile proteins (actin and myosin), and structural proteins (titin, nebulin, and desmin). Thus, not all cells are the same, as we will see. However, most cells have three major subdivisions: the *plasma membrane*, which encloses the cells; the **nucleus**, which contains the cell's genetic material; and the **cytoplasm**, the portion of the cell's interior not occupied by the nucleus but containing numerous organelles, structural proteins, transport and secretory vesicles, and enzymes. A summary of cell structures and functions can be found in Table 2-2.

2.3 Cellular Metabolism

The term **intermediary metabolism** refers collectively to the large set of chemical reactions inside the cell that involve the degradation, synthesis, and transformation of small organic molecules, such as simple sugars, amino acids, and fatty acids. These reactions are critical for ultimately capturing energy to be used for cell activities and for providing the raw materials needed for maintaining the cell's structure and function and for the cell's growth. All intermediary metabolism occurs in the cytoplasm, with most of it accomplished in the cytosol. The cytosol contains thousands of enzymes involved in glycolysis and other intermediary biochemical reactions.

Cells are incredibly dynamic and are constantly doing things related to their primary functions as well as their housekeeping chores to keep the cells alive and well. In order for this to occur, cells must be both making things that are needed and breaking down things that are not. **Anabolic** processes are those that favour the synthesis of molecules for building up organs and tissues. In contrast, **catabolic** processes are those that favour the breakdown of complex molecules into more simple ones. It is important to understand that cells are simultaneously undergoing both anabolism and catabolism and that these processes may be balanced or that one of the states is favoured, depending on the demands of the cell at any given time. Anabolic processes,

■ **TABLE 2-2** Summary of Cell Structures and Functions

Cell Part	Structure	Function
Plasma membrane	Lipid bilayer studded with proteins and small amounts of carbohydrate	Acts as selective barrier between cellular contents and extracellular fluid; controls traffic in and out of the cell
Nucleus	DNA and specialized proteins enclosed by a double-layered membrane	Acts as control centre of the cell, providing storage of genetic information; nuclear DNA provides codes for the synthesis of structural and enzymatic proteins and serves as blueprint for cell replication
Cytoplasm		
<i>Organelles</i>		
Endoplasmic reticulum	Extensive, continuous membranous network of fluid-filled tubules and flattened sacs, partially studded with ribosomes	Forms new cell membrane and other cell components and manufactures products for secretion
Golgi complex	Sets of stacked, flattened membranous sacs	Modifies, packages, and distributes newly synthesized proteins
Lysosomes	Membranous sacs containing hydrolytic enzymes	Serve as digestive system of the cell, destroying foreign substances and cellular debris
Centriole	Usually paired, small barrel-shaped organelles that consist of nine short triplet microtubules	Site of growth of new microtubules: both cytoplasmic transport microtubules and the microtubules that form the mitotic spindle
Peroxisomes	Membranous sacs containing oxidative enzymes	Perform detoxification activities
Mitochondria	Rod- or oval-shaped bodies enclosed by two membranes, with the inner membrane folded into cristae that project into an interior matrix	Act as energy-producing organelles; major sites of ATP production; contain enzymes for citric acid cycle and electron transport chain
Vaults	Shaped like hollow octagonal barrels	Serve as cellular trucks for transport from nucleus to cytoplasm
<i>Cytosol: gel-like portion</i>		
Intermediary metabolism enzymes	Dispersed within the cytosol	Facilitate intracellular reactions involving the degradation, synthesis, and transformation of small organic molecules
Ribosomes	Granules of RNA and proteins—some attached to rough endoplasmic reticulum, some free in the cytoplasm	Serve as workbenches for protein synthesis
Transport, secretory, and endocytotic vesicles	Transiently formed, membrane-enclosed products synthesized within or engulfed by the cell	Transport and/or store products being moved within, out of, or into the cell, respectively
Inclusions	Glycogen granules, fat droplets	Store excess nutrients
<i>Cytosol: cytoskeleton portion</i>		As an integrated whole, serves as the cell's "bone and muscle"
Microtubules	Long, slender, hollow tubes composed of secretory vesicles	Maintain asymmetric cell shapes and tubulin molecules; coordinate complex cell movements, specifically facilitating transport of secretory vesicles within cells, serving as main structural and functional component of cilia and flagella, and forming mitotic spindle during cell division
Microfilaments	Intertwined helical chains of actin molecules; microfilaments composed of myosin molecules also present in muscle cells	Play a vital role in various cellular contractile systems, including muscle contraction and amoeboid movement; serve as a mechanical stiffener for microvilli
Intermediate filaments	Irregular, threadlike proteins	Help resist mechanical stress

in particular, put a demand on the cell. For a cell to make more complex molecules, the building blocks must be present. If a cell is not capable of creating these building blocks itself, it must transport such molecules from the extracellular environment into the cell. Once inside, the cell is then capable of combining these precursor molecules into more complex ones. However, in addition to these precursor molecules, anabolic metabolism has an additional requirement: it takes energy to combine simpler molecules into more complex molecules.

The source of energy for the body is the chemical energy stored in the carbon bonds of ingested food. Body cells are not equipped to use this energy directly; the energy must be extracted from the food nutrients and converted into a usable form of energy—namely, the high-energy phosphate bonds of **adenosine triphosphate (ATP)**. Adenosine triphosphate consists of adenosine with three phosphate groups attached (*tri* means “three”) (see Appendix B, p. A-17). When a high-energy bond, such as that binding the terminal phosphate to adenosine, is split, a substantial amount of energy is released. Adenosine triphosphate is the universal energy carrier—the common energy “currency” of the body. Cells use ATP to pay for the cost of operating the body’s cells (in essence, the cost of cellular work). To obtain immediate usable energy, cells split the terminal phosphate bond of ATP, which yields **adenosine diphosphate (ADP)**—adenosine with two phosphate groups attached (*di* means “two”)—plus inorganic phosphate (P_i), plus energy:

In this energy scheme, food can be thought of as the crude fuel, and ATP the refined fuel for operating the body’s machinery. In this fuel-conversion process, dietary food is digested, or broken down, by the digestive system into smaller absorbable units that can be transferred from the digestive tract lumen into the blood (see Chapter 15). For example, dietary carbohydrates are broken down primarily into glucose, which is absorbed into the blood. No usable energy is released during the digestion of food. When delivered to the cells by the blood, the nutrient molecules are transported across the plasma membrane into the cytosol (described in Sections 2.6–2.8) where they are available for ATP production.

The chemical pathways for the production of ATP involve three separate processes: *substrate-level phosphorylation*, *anaerobic glycolysis*, and *aerobic metabolism*. In most cells, the majority of ATP is generated from the sequential dismantling of absorbed nutrient molecules in four steps: (1) *glycolysis* (both aerobic and anaerobic), (2) the decarboxylation of pyruvate, (3) the *tricarboxylic acid cycle* (TCA cycle; aerobic), and (4) the *electron transport chain* (ETC; aerobic). We will use glucose as an example to describe these four steps in ATP production (► Figure 2-1). However, before focusing on glycolysis and the mitochondrial ATP-generating processes, we first discuss substrate-level phosphorylation, which is completed in the cytosol of skeletal muscle and brain cells for immediate ATP generation, such as at the onset of intense exercise.

► **FIGURE 2-1 An overview of ATP production from glucose.** ATP production starts in the cytoplasm with the process of glycolysis to form pyruvate, which can be decarboxylated to form acetyl CoA. Acetyl CoA enters the mitochondrial tricarboxylic acid cycle. The NADH and FADH₂ molecules produced can enter the mitochondrial electron transport chain to produce even more ATP. Altogether, the maximum theoretical yield of ATP from 1 molecule of glucose is 38 ATP.

Pathways for production of ATP

SUBSTRATE-LEVEL PHOSPHORYLATION

In some tissues, such as skeletal muscle, ATP appears in relatively low concentrations. This means that even small decreases in ATP content can be problematic for cellular operation. Therefore, ATP production is closely regulated. The first step in ATP generation is the substrate-level phosphorylation of ADP using creatine phosphate (CP). **Creatine phosphate** (a.k.a. phosphocreatine) is the first energy store tapped at the onset of contractile activity. It is not stored in the mitochondria, but rather in the cytosol of the cell. Like ATP, CP contains a high-energy phosphate group. Just as energy is released when the terminal phosphate bond in ATP is spliced, similar energy is released when the bond between phosphate and creatine is broken. The energy released from the hydrolysis (a reaction using H₂O) of CP, along with the phosphate, can be donated directly to ADP to form ATP. This reaction, which is catalyzed by the skeletal muscle cell enzyme **creatine kinase**, is reversible; energy and phosphate from ATP can be transferred to creatine to form CP:

In accordance with the law of mass action, as energy reserves are built up in a resting skeletal muscle, the increased concentration of ATP favours transfer of the high-energy phosphate group from ATP to form CP. By contrast, at the onset of muscle contraction, when myosin ATPase (the enzyme on the myosin head; see Chapter 7) splits the meagre reserves of ATP, the resultant fall in ATP concentration favours transfer of the high-energy phosphate group from stored CP to form more ATP. A rested muscle contains about five times as much CP

(18 mM per kg of muscle) as ATP. Thus, most energy stored in skeletal muscle is in the form of CP. When the skeletal muscle starts to vigorously contract using ATP to accomplish the cellular work, the CP replenishes the ATP, preserving the level of ATP in the working skeletal muscle. Therefore, CP levels tend to decrease more greatly than ATP levels. There tends to be a large change in CP levels with a minimal change in the level of ATP. Because only one enzymatic reaction is involved in this energy transfer, ATP can be formed rapidly (within a fraction of a second) by using CP.

GLYCOLYSIS

Among the thousands of enzymes within the cytosol are those responsible for **glycolysis**, a chemical process involving ten separate sequential reactions that break down the simple sugar molecule, glucose, into two pyruvic acid molecules (*glyc-* means “sweet”; *lysis* means “break down”). During glycolysis, some of the energy from the broken chemical bonds of glucose is used to directly convert ADP into ATP (▶ Figure 2-2) while also producing NADH. However, glycolysis is not very efficient in terms of energy extraction: the net yield is only two molecules of ATP and two molecules of NADH per glucose molecule processed. Much of the energy originally contained in the glucose molecule is still locked in the chemical bonds of the pyruvic acid molecules. The low-energy yield of glycolysis is not enough to support the body’s demand for ATP. This is where the mitochondria come into play.

There are numerous metabolic diseases that can affect glycolysis. Persons with McArdle disease, for example, are unable to break down glycogen to glucose and thereby produce energy. (This disease was named after Brian McArdle, a British physician who in 1951 discovered a muscle disorder that caused cramp-like pains yet was not associated with the normal production of lactic acid from exercise. The defect was later identified as an absence of phosphorylase, the enzyme involved in the first step in the splitting-off of the glucose-1-phosphate units from glycogen.) The symptoms of McArdle disease include muscle fatigue, pain, and cramps. These are due to a deficiency of the skeletal muscle form of glycogen phosphorylase (enzyme) and result in the unavailability of muscle glycogen as a source of energy for muscle contraction. Once diagnosed, McArdle disease may be treated by correcting the enzyme deficiency. One such treatment is gene-replacement therapy, using the adenovirus vector.

▶ **FIGURE 2-2 A simplified summary of glycolysis.** Glycolysis involves the breakdown of glucose into two pyruvic acid molecules, with a net yield of two molecules of ATP for every glucose molecule processed.

PYRUVATE DECARBOXYLATION

Pyruvic acid, which is produced in the cytosol of the cell via glycolysis, enters the mitochondrial matrix through the carrier protein monocarboxylate transporter, which is located on the inner mitochondrial membrane. Once inside, pyruvate is metabolized by the pyruvate dehydrogenase complex and is decarboxylated. Decarboxylation is the removal of a carbon and the formation of carbon dioxide (CO_2), as well as the transfer of a hydrogen to nicotinamide adenine dinucleotide (NAD^+), forming NADH (discussed in the section Electron Transport Chain). Carbon dioxide is eliminated from the body via the cardiorespiratory system. Once the pyruvate is converted to acetyl coenzyme A (acetyl CoA), it is ready to enter the TCA cycle.

TRICARBOXYLIC ACID CYCLE

Acetyl CoA enters the **tricarboxylic acid cycle** (also known as the **Krebs cycle** or the **citric acid cycle**), which consists of a series of eight separate biochemical reactions that are directed by the enzymes of the mitochondrial matrix. ▶ Figure 2-3 is a schematic of a TCA cycle, which is one way to characterize a series of biochemical reactions. (The molecules themselves are not physically moved around in a cycle.) Acetyl CoA is a two-carbon molecule that enters the TCA cycle and combines with oxaloacetic acid (a four-carbon molecule) to form a six-carbon molecule, citric acid (hence the name citric acid cycle). Coenzyme A is removed from the acetyl CoA, allowing it to be reused in the conversion of more pyruvic acid into acetyl CoA. Next, the atoms of the citric acid are rearranged to become isocitric acid. Isocitric acid then becomes alpha-ketoglutaric acid, in a two-reaction process: first, a hydrogen is removed, and then a carbon, via CO_2 . Then, hydrogen is again removed, and CO_2 forms. The new structure then attaches itself to coenzyme A, forming succinyl CoA. Succinyl CoA consists of four carbons.

The next molecular arrangement is the only reaction in the TCA cycle that forms ATP directly. Coenzyme A is removed and a phosphate group is added. This group is transferred later via guanosine triphosphate (GTP) to ADP, forming ATP. In the following steps, more hydrogen is removed (forming fumaric acid), water is added (forming malic acid), and then more hydrogen is again removed (forming oxaloacetic acid). This last removal of hydrogen and acceptance of hydrogen by NAD^+ forms the molecule that we initially began with: oxaloacetic acid. As the cycle progresses, different molecules are formed. These molecular alterations have the following important consequences:

1. Two carbons are sequentially removed from the six-carbon citric acid molecule, converting it back into the four-carbon oxaloacetic acid, which is now available at the top of the cycle to pick up another acetyl CoA for another revolution through the cycle.
2. The released carbon atoms, which were originally present in the acetyl CoA that entered the cycle, are converted into two molecules of CO_2 . This CO_2 , as well as the

FIGURE 2-3 Tricarboxylic acid cycle. This simplified version of the TCA cycle shows how the two carbons entering the cycle by means of acetyl CoA are eventually converted into carbon dioxide, and how oxaloacetic acid, which accepts acetyl CoA, is regenerated at the end of the cyclical pathway. Also denoted is the release of hydrogen atoms at specific points along the pathway. These hydrogens bind to the hydrogen carrier molecules NAD^+ and FAD for further processing by the electron transport chain. One molecule of ATP is generated for each molecule of acetyl CoA that enters the TCA cycle, yielding a total of two molecules of ATP for each molecule of processed glucose.

CO_2 produced during the formation of acetic acid from pyruvic acid, passes out of the mitochondrial matrix and subsequently out of the cell to enter the blood. In turn, the blood carries the CO_2 to the lungs, where it is finally eliminated into the atmosphere through the process of breathing (see Chapter 12). The oxygen used to make CO_2 from these released carbon atoms is derived from the molecules that were involved in the reactions, not from free molecular oxygen supplied by breathing.

3. Hydrogen atoms are also removed during the cycle at four of the chemical conversion steps. The key purpose of the

citric acid cycle is to produce these hydrogens for entry into the electron transport chain. These hydrogens are “caught” by two other compounds that act as hydrogen carrier molecules: **nicotinamide adenine dinucleotide (NAD^+)**, a derivative of the B vitamin niacin; and **flavine adenine dinucleotide (FAD)**, a derivative of the B vitamin riboflavin. The transfer (or addition) of hydrogen converts these compounds to NADH and FADH_2 , respectively.

4. One more molecule of ATP is produced for each molecule of acetyl CoA processed. Actually, ATP is

not directly produced by the citric acid cycle. The released energy is used to directly link inorganic phosphate to **guanosine diphosphate (GDP)** to form **guanosine triphosphate (GTP)**, a high-energy molecule similar to ATP. The energy from GTP is then transferred to ATP as follows:

Because each glucose molecule is converted into two acetyl CoA molecules, permitting two turns of the TCA cycle, two more ATP molecules are produced from each glucose molecule.

So far the cell still does not have much of an energy profit. However, the citric acid cycle is important in preparing the hydrogen carrier molecules for their entry into the next step, the electron transport chain, which produces far more energy than the sparse amount of ATP produced by the cycle itself.

ELECTRON TRANSPORT CHAIN

Most of the potential energy is still stored in the released hydrogen atoms, which contain electrons at high energy levels. The “big payoff” comes when NADH and FADH₂ enter the **electron transport chain**, which consists of electron carrier molecules located in the inner mitochondrial membrane lining the cristae (► Figure 2-4). The high-energy electrons are extracted from the hydrogens held in NADH and FADH₂ and are transferred through a series of steps from one electron-carrier

molecule—complexes I–IV, the quinone pool (Q), and cytochrome c (C)—to another, within the cristae membrane, in a kind of assembly line (► Figure 2-4). As a result of giving up hydrogen and electrons within the electron transport chain, NADH and FADH₂ are converted back to NAD⁺ and FAD. These molecules are now free to pick up more hydrogen atoms released during glycolysis and the citric acid cycle. Thus, NAD⁺ and FAD serve as the link between TCA and the electron transport chain.

During the process of moving the high-energy electrons down the electron transport chain, some of the energy is used to pump hydrogen ions across the inner mitochondrial membrane. This occurs at three different places and leads to the accumulation of hydrogen ions within the intermembrane space. It is this accumulation of hydrogen ions that leads to the generation of ATP by what is known as the **chemiosmotic mechanism**. The enzyme **ATP synthase** is also located within the inner mitochondrial membrane, and it is activated by the flow of hydrogen ions back into the matrix from the inner mitochondrial membrane. Once activated, ATP synthase creates ATP from ADP + P_i in a process called **oxidative phosphorylation**. The amount of ATP that can be produced from high-energy electron carriers depends on where they enter the electron transport chain. For example, NADH enters the electron transport chain early, and each molecule of NADH can lead to the production of three ATP molecules, whereas FADH₂ enters the electron transport chain at a later stage and can only produce two ATP molecules.

► **FIGURE 2-4** Oxidative phosphorylation at the mitochondrial inner membrane. ATP synthesis that results from the passage of high-energy electrons through the mitochondrial electron transport chain and the activation of ATP-synthase by movement of H⁺.

HOW MUCH ATP IS REALLY PRODUCED FOR EACH GLUCOSE?

Although the processes that lead to the formation of ATP seem relatively straightforward, defining the exact quantity of ATP that can be produced from each glucose is not. So far we have examined the theoretical maximum of the amount of ATP that can be produced, which is 38 ATP molecules (see ► Figure 2-1). This theoretical maximum makes two primary assumptions (1) that the NADH produced within the cytosol during glycolysis can be transported without cost of energy into the mitochondria to enter the electron transport chain, and (2) that the electron transport chain always runs at 100 percent efficiency.

Although several carrier systems exist to move cytosolic NADH into the mitochondria, not all of them are able to directly shuttle NADH without expending energy. Some of these systems require active transport and actually consume ATP to move the NADH. Others result in the conversion of cytosolic NADH to mitochondrial FADH₂,

both of which reduce the total number of ATP molecules that can be produced from each glucose.

The electron transport system itself does not operate at maximum efficiency. When NADH enters the electron transport chain, it ultimately leads to the production of two or three ATP molecules, so the value of 2.5 is generally used. Similarly, FADH_2 is said to produce 1.5 ATP molecules since it actually produces either one or two ATP molecules.

So taking altogether the amount of ATP, NADH, and FADH_2 produced from each glucose molecule (see ▶ Figure 2-1), we can determine that the actual amount of ATP produced for each glucose molecule is somewhere between 30 and 32, depending on how the energy stored in the NADH from glycolysis ultimately ends up entering the electron transport chain.

Aerobic versus anaerobic conditions

All of our discussion so far on the production of ATP from glucose has focused on **aerobic** metabolism, which requires the presence of oxygen for these reactions to occur. What happens when O_2 is not present? When O_2 levels are insufficient to maintain aerobic metabolism, **anaerobic** (lack of air, specifically lack of O_2) metabolism becomes the predominant source of energy (▶ Figure 2-5). Recall that the first step of ATP production, glycolysis, takes place in the cytosol and involves the breakdown of glucose into pyruvic acid, producing a low yield of two molecules of ATP and one molecule of NADH per molecule of glucose. Glycolysis is always considered anaerobic since the conversion of glucose to pyruvate does not require the presence of O_2 . However, the intermediate reactions that lead to the decarboxylation of pyruvate to acetyl CoA do require O_2 to proceed. The result is that in the absence of O_2 , pyruvate is instead converted to lactic acid (▶ Figure 2-5), which does not enter the mitochondria or the TCA cycle for further ATP production. The conversion of pyruvate to lactic acid consumes NADH, negating the NADH produced during glycolysis, which further decreases the amount of ATP produced during anaerobic metabolism.

▶ **FIGURE 2-5 Comparison of high-energy products under anaerobic and aerobic conditions.** In the absence of O_2 , pyruvate cannot be converted into acetyl CoA, and lactic acid is produced instead, dramatically reducing the number of high-energy products available for ATP production.

ATP production from other dietary sources

Glucose, the principal nutrient derived from dietary carbohydrates, is the fuel preference of most cells. However, nutrient molecules derived from fats (fatty acids) and, if necessary, from protein (amino acids) can also participate at specific points in this overall chemical reaction to eventually produce energy. Amino acids are usually used for protein synthesis instead of energy production, but they can be used as fuel if insufficient glucose and fat are available. Details of these processes are discussed in Chapter 16.

Note that the oxidative reactions within the mitochondria generate energy, unlike the oxidative reactions controlled by the peroxisome enzymes. Both organelles use oxygen, but for different purposes.

ATP for synthesis, transport, and mechanical work

Once formed, ATP is transported out of the mitochondria and is then available as an energy source as needed within the cell. Cell activities that require energy expenditure fall into three main categories:

1. *Synthesis of new chemical compounds*, such as protein synthesis by the endoplasmic reticulum. Some cells, especially cells with a high rate of secretion and cells in the growth phase, use up to 75 percent of the ATP they generate just to synthesize new chemical compounds.
2. *Membrane transport*, such as the selective transport of molecules across the kidney tubules during the process of urine formation. Kidney cells can expend as much as 80 percent of their ATP currency to operate their selective membrane-transport mechanisms.
3. *Mechanical work*, such as contraction of the heart muscle to pump blood or the contraction of skeletal muscles to lift an object. These activities require tremendous quantities of ATP.

As a result of cell energy expenditure to support these various activities, large quantities of ADP are produced. These energy-depleted ADP molecules enter the mitochondria for recharging by participating in oxidative phosphorylation before cycling back into the cytosol as energy-rich ATP molecules. In this recharging–expenditure cycle, a single ADP/ATP molecule may shuttle back and forth between the mitochondria and the cytosol.

The high demands for ATP make glycolysis alone an insufficient and inefficient supplier of power for most cells. Were it not for the mitochondria, which house the metabolic machinery for oxidative phosphorylation, the body's energy capability would be very limited. However, glycolysis does provide cells with a sustenance

mechanism that can produce at least some ATP under anaerobic conditions. Skeletal muscle cells in particular take advantage of this ability during short bursts of strenuous exercise, when energy demands for contractile activity outstrip the body's ability to produce ATP at a fast enough rate through oxidative phosphorylation. Even though a single pass through glycolysis produces less ATP than oxidative phosphorylation, the high flux rate of glucose to either pyruvate or lactate can produce ATP much faster. As well, red blood cells, which are the only cells that do not contain any mitochondria, rely solely on glycolysis for their limited energy production. The energy needs of red blood cells are low, however, because they also lack a nucleus and therefore are not capable of synthesizing new substances, which is the biggest energy expenditure for most noncontractile cells.

1. State how much ATP can be generated for each glucose molecule.
2. Compare aerobic and anaerobic ATP production.

2.4 | The Plasma Membrane

The survival of every cell depends on the maintenance of intracellular contents unique for that cell type, despite the remarkably different composition of the extracellular fluid surrounding it. This difference in fluid composition inside and outside a cell is maintained by the plasma membrane, an extremely thin layer of lipids and proteins that forms the outer boundary of every cell and encloses the intracellular contents. In addition to serving as a mechanical barrier that traps needed molecules within the cell, the plasma membrane plays an active role in determining the composition of the cell by selectively permitting specific substances to pass between the cell and its environment. Besides controlling the entry of nutrient molecules and the exit of secretory and waste products, the plasma membrane maintains differences in ion concentrations between a cell's interior and exterior. These ionic differences, as you will learn, are important in the electrical activity of the plasma membrane. As well, the plasma membrane participates in the joining of cells to form tissues and organs. Furthermore, it plays a key role in the ability of a cell to respond to changes, or signals, in the cell's environment. This ability is important in communication between cells. For every cell type, these membrane functions are important to (1) the cell's survival, (2) its ability to maintain homeostasis, and (3) its ability to function cooperatively and in coordination with surrounding cells. Many of the functional differences between cell types are due to subtle variations in the composition of their plasma membranes, which in turn enable different cells to interact in different ways with essentially the same extracellular fluid environment. If problems occur in the membrane of the cell, the ramifications can be very serious. (To understand what can happen when there are problems with the cell membrane, see Concepts, Challenges, and Controversies; p. 32).

► **FIGURE 2-6** Trilaminar appearance of a plasma membrane in an electron micrograph. Depicted are the plasma membranes of two adjacent cells. Note that each membrane appears as two dark layers separated by a light middle layer.

The plasma membrane is too thin to be seen under an ordinary light microscope, but with an electron microscope it appears as a **trilaminar structure** consisting of two dark layers separated by a light middle layer (*tri* means “three”; *lamina* means “layer”) (► Figure 2-6). The specific arrangement of the molecules that make up the plasma membrane is responsible for this three-layered “sandwich” appearance.

Membrane structure and composition

The plasma membrane consists of mostly lipids (fats), proteins, and some carbohydrates. The most abundant membrane lipids are phospholipids, with lesser amounts of cholesterol. Approximately a billion phospholipid molecules are present in the plasma membrane of a typical human cell. **Phospholipids** have a polar (electrically charged; see Appendix B, p. A-13) head containing a negatively charged phosphate group and two non-polar (electrically neutral) fatty acid tails (► Figure 2-7a). The polar end is **hydrophilic** (water loving) because it can interact with water molecules, which are also polar; the nonpolar end is **hydrophobic** (water fearing) and will not mix with water. Such two-sided molecules self-assemble into a **lipid bilayer**, a double layer of lipid molecules, when in contact with water (► Figure 2-7b) (*bi* means “two”). The hydrophobic tails bury themselves in the centre away from the water, whereas the hydrophilic heads line up on both sides in contact with the water. The outer surface of the layer is exposed to extracellular fluid (ECF), whereas the inner surface is in contact with the intracellular fluid (ICF) (► Figure 2-7c).

The lipid bilayer is not a rigid structure but is fluid in nature. The phospholipids, which are not held together by strong chemical bonds, can twirl around rapidly as well as move about within their own half of the layer. This phospholipid movement accounts in large part for membrane fluidity.

Cholesterol also contributes to the fluidity as well as the stability of the membrane. The cholesterol molecules are tucked in between the phospholipid molecules, where they prevent the fatty acid chains from packing together and crystallizing, a process that would drastically reduce membrane fluidity.

► **FIGURE 2-7** Structure and organization of phospholipid molecules in a lipid bilayer. (a) Phospholipid molecule. (b) In water, phospholipid molecules organize themselves into a lipid bilayer with the polar heads interacting with the polar water molecules at each surface and the nonpolar tails all facing the interior of the bilayer. (c) An exaggerated view of the plasma membrane enclosing a cell, separating the ICF from the ECF

Cholesterol's spatial relationship with phospholipid molecules helps stabilize the phospholipids' positions.

Because of its fluid nature, the plasma membrane has structural integrity but at the same time is flexible, enabling the cell to change shape. For example, muscle cells change shape as they

contract, and red blood cells must change shape considerably as they travel through the capillaries, the tiniest of blood vessels.

The **membrane proteins** are attached to or inserted within the lipid bilayer (► Figure 2-8). Some of these proteins extend through the entire thickness of the membrane. Other proteins stud only the outer or inner surface; they are anchored by interactions with a protein that spans the membrane or by attachment to the lipid bilayer. The plasma membrane contains approximately 50 times as many lipid molecules as protein molecules; however, protein accounts for approximately half of the membrane's mass, since protein molecules are so large. The fluidity of the lipid bilayer enables many membrane proteins to move within the membrane, although the cytoskeleton restricts the mobility of proteins that perform a specialized function in a specific area of the cell. This view of membrane structure is known as the **fluid mosaic model**, in reference to the membrane fluidity and the ever-changing mosaic pattern of the proteins embedded within the lipid bilayer. (A mosaic is a surface decoration made by inlaying small pieces of variously coloured tiles to form patterns or pictures.)

The small amount of membrane carbohydrate is located on the outer surface, making the plasma membrane "sugar coated." Short-chain carbohydrates protrude like tiny antennas from the outer surface, bound primarily to membrane proteins and, to a lesser extent, to lipids. These sugary combinations are known as *glycoproteins* and *glycolipids*, respectively (► Figure 2-8).

The different components of the plasma membrane carry out a variety of functions, including the following: (1) the lipid bilayer acts as a barrier to diffusion, (2) proteins perform specialized functions, and (3) carbohydrates act as self-recognition molecules for cell-to-cell interaction. Let's look at these functions in more detail.

LIPID BILAYER

The lipid bilayer serves three important functions:

1. It forms the basic structure of the membrane. The phospholipids can be visualized as the "pickets" that form the "fence" around the cell.
2. Its hydrophobic interior serves as a barrier to passage of water-soluble substances between the ICF and ECF. Water-soluble substances cannot dissolve in and pass through the lipid bilayer. By means of this barrier, the cell can maintain different mixtures and concentrations of solutes inside and outside the cell.
3. It is responsible for the fluidity of the membrane.

MEMBRANE PROTEINS

Different types of membrane proteins serve the following specialized functions:

1. Some proteins span the membrane to form water-filled pathways, or channels, across the lipid bilayer (► Figure 2-8). Water-soluble substances small enough to enter a channel can pass through the membrane this way without coming into direct contact with the hydrophobic lipid interior. Only small ions can fit through channels as

► **FIGURE 2-8 Fluid mosaic model of plasma membrane structure.** The plasma membrane comprises a lipid bilayer embedded with proteins. Some of these proteins extend through the thickness of the membrane, some are partially submerged in the membrane, and others are loosely attached to the surface of the membrane. Short carbohydrate chains are attached to proteins or lipids on the outer surface only.

their small diameter precludes passage of particles greater than 0.8 nm in diameter. Furthermore, a given channel can selectively attract or repel particular ions. For example, only sodium (Na^+) can pass through Na^+ channels, whereas only potassium (K^+) can pass through K^+ channels. This selectiveness is due to specific arrangements of chemical groups on the interior surfaces of the proteins that form the channel walls. A given channel may even be open or closed to its specific ion as a result of changes in channel shape in response to a controlling mechanism, for example, glucose uptake by muscle cells (p. 273). This is a good example of function depending on structural details. Cells vary in number, kind, and activity of channels they possess.

2. Another group of proteins that spans the membrane serves as **carrier molecules**, which transfer specific substances across the membrane that are unable to cross on their own. How carriers accomplish this transport will be described in Section 2.8. (Thus, channels and carrier molecules are both important in the transport of substances between the ECF and ICF.) Each carrier can transport only a particular molecule or closely related molecules. Cells of different types have different kinds of carriers. As a result, they vary as to which substances they can selectively transport across their membranes. For example, thyroid gland cells are the only cells in the body to use iodine. Appropriately, only the

plasma membranes of thyroid gland cells have carriers for iodine, so these cells alone can transport this element from the blood into the cell interior.

3. Other proteins located on the inner membrane surface serve as **docking-marker acceptors** that bind in a lock-and-key fashion with the docking markers of secretory vesicles. Secretion is initiated when stimulatory signals trigger the fusion of the secretory vesicle membrane with the inner surface of the plasma membrane through interactions between these matching labels. The secretory vesicle subsequently opens up and empties its contents to the outside by exocytosis.
4. Another group of surface-located proteins function as **membrane-bound enzymes** that control specific chemical reactions at either the inner or the outer cell surface. Cells are specialized in the types of enzymes embedded within their plasma membranes. For example, the outer layer of the plasma membrane of skeletal muscle cells contains an enzyme that destroys the chemical messenger that triggers muscle contraction, thus enabling the muscle to relax.
5. Many proteins on the outer surface serve as **receptor sites** (or, simply, **receptors**) that “recognize” and bind with specific molecules in the cell’s environment. This binding initiates a series of membrane and intracellular events that alter the activity of the particular cell. In this way,

Cystic Fibrosis: A Fatal Defect in Membrane Transport

2

APPROXIMATELY ONE IN EVERY 3500 CHILDREN IS BORN with cystic fibrosis (CF). It is characterized by the production of abnormally thick, sticky mucus. Most dramatically affected are the respiratory airways and the pancreas.

Respiratory Problems

The presence of the thick, sticky mucus in the respiratory airways makes it difficult to get adequate air in and out of the lungs. And because bacteria thrive in the accumulated mucus, CF patients suffer from repeated respiratory infections. They are especially susceptible to *Pseudomonas aeruginosa*, an “opportunistic” bacterium that is frequently present in the environment but usually causes infection only when some underlying problem handicaps the body’s defences. Gradually, the involved lung tissue becomes scarred (fibrotic), making the lungs harder to inflate. This complication increases the work of breathing beyond the extra work required to move air through the clogged airways.

Underlying Cause

During the last decade, researchers found that cystic fibrosis is caused by any one of several different genetic defects that lead to production of a flawed version of a protein known as *cystic fibrosis transmembrane conductance regulator* (CFTR). CFTR normally helps form and regulate the chloride (Cl^-) channels in the plasma membrane. With CF, the defective CFTR “gets stuck” in the endoplasmic reticulum/Golgi system, which normally manufactures and processes this product and ships it to the plasma membrane (p. 48). That is, in CF patients, the mutated version of CFTR is only partially processed and never makes

it to the cell surface. The resultant absence of CFTR protein in the plasma membrane’s Cl^- channels leads to membrane impermeability to Cl^- . Because Cl^- transport across the membrane is closely linked to sodium ion (Na^+) transport, cells lining the respiratory airways cannot absorb salt (NaCl) properly. As a result, salt accumulates in the fluid lining the airways.

What has puzzled researchers is how this Cl^- channel defect and resultant salt accumulation lead to the excess mucus problem. Two recent discoveries have perhaps provided an answer, although these proposals remain to be proven and research into other possible mechanisms continues to be pursued. One group of investigators found that the airway cells produce a natural antibiotic, *defensin*, which normally kills most of the inhaled airborne bacteria. It turns out that defensin cannot function properly in a salty environment. Bathed in the excess salt associated with CF, the disabled antibiotic cannot rid the lungs of inhaled bacteria. This leads to repeated infections. One of the outcomes of the body’s response to these infections is excess production of mucus. In turn, this mucus serves as a breeding ground for more bacterial growth. The cycle continues as the lung-clogging accumulation of mucus and the frequency of lung infections grow ever worse. The excess mucus is also especially thick and sticky, making it difficult for the normal ciliary defence mechanisms of the lung to sweep up the bacteria-laden mucus from the lungs. The mucus is thick and sticky because it is underhydrated (has too little water), a problem believed to be linked to the defective salt transport.

The second new study found an additional complicating factor in the CF story. These researchers demonstrated that CFTR appears to

chemical messengers in the blood, such as water-soluble hormones, can influence only the specific cells that have receptors for a given messenger. Even though every cell is exposed to the same messengers via their widespread distribution by the blood, a given messenger has no effect on cells that do not have receptors for this specific messenger. For example, the anterior pituitary gland secretes into the blood thyroid-stimulating hormone (TSH), which can attach only to the surface of thyroid gland cells to stimulate secretion of thyroid hormone. No other cells have receptors for TSH, so only thyroid cells are influenced by TSH, despite its widespread distribution.

6. Still other proteins serve as **cell adhesion molecules (CAMs)**. Many CAMs protrude from the outer membrane surface and form loops or hooks that the cells use to grip each other and to grasp the connective tissue fibres that

interlace between cells. For example, **cadherins**, on the surface of adjacent cells, interlock in a zipper-like fashion to help hold the cells within tissues and organs together. Some CAMs, such as the **integrins**, span the plasma membrane. Integrins not only serve as a structural link between the outer membrane surface and its extracellular surroundings but also connect the inner membrane surface to the intracellular cytoskeletal scaffolding. These CAMs mechanically link the cell’s external environment and intracellular components. Furthermore, integrins can also relay regulatory signals through the plasma membrane in either direction. Although CAMs originally were believed to serve only as adhesive molecules, investigators have now learned that some of them also act as **signalling molecules**. These CAMs participate in signalling cells to grow and in signalling immune system cells to interact

serve a dual role as a Cl^- channel and as a membrane receptor that binds with *P. aeruginosa* (and perhaps other bacteria). CFTR subsequently destroys the captured bacteria. In the absence of CFTR in the airway cell membranes of CF patients, *P. aeruginosa* is not cleared from the airways as usual. In a double onslaught, these bacteria were shown to trigger the airway cells to produce unusually large amounts of an abnormally thick, sticky mucus. This mucus promotes more bacterial growth, as the vicious cycle continues.

Canadian researcher Dr. Han-Peter Hauber and associates from McGill University have suggested that the increased production of mucus may be associated with our immune system. Mucus overproduction by the epithelium in patients with cystic fibrosis could be regulated by increased expression of interleukin-9 (IL-9) and the IL-9 receptor (IL-9R), as well as upregulation of calcium-activated chloride channel hCLCA1, which may be a new way to control mucus overproduction in cystic fibrosis patients.

Pancreatic Problems

Furthermore, in CF patients, the pancreatic duct, which carries secretions from the pancreas to the small intestine, becomes plugged with thick mucus. Because the pancreas produces enzymes important in the digestion of food, malnourishment eventually results. In addition, as the pancreatic digestive secretions accumulate behind the blocked pancreatic duct, fluid-filled cysts form in the pancreas, with the affected pancreatic tissue gradually degenerating and becoming fibrotic. The name “cystic fibrosis” aptly describes long-term changes that occur in the pancreas and lungs as the result of a single genetic flaw in CFTR.

with the right kind of other cells during inflammatory responses and wound healing, among other things.

7. Finally, still other proteins on the outer membrane surface, especially in conjunction with carbohydrates (as glycoproteins), are important in the cells’ ability to recognize “self” (i.e., cells of the same type) and in cell-to-cell interactions.

SELF-RECOGNITION

The short sugar chains on the outer membrane surface serve as self-identity markers that enable cells to identify and interact with one another in the following ways:

1. Different cell types have different markers. The unique combination of sugar chains projecting from the surface membrane proteins serves as the trademark of a particular cell type,

Treatment

Treatment consists of physical therapy to help clear the airways of the excess mucus and antibiotic therapy to combat respiratory infections, plus special diets and administration of supplemental pancreatic enzymes to maintain adequate nutrition. Despite this supportive treatment, most CF victims do not survive beyond their early 30s, with most dying from lung complications.

With the recent discovery of the genetic defect responsible for the majority of CF cases, investigators are hopeful of developing a means to correct or compensate for the defective gene. Another potential cure being studied is the development of drugs that induce the mutated CFTR to be “finished off” and inserted in the plasma membrane. Furthermore, several promising new drug-therapy approaches, such as a mucus-thinning aerosol drug that can be inhaled, offer hope of reducing the number of lung infections and extending the lifespan of CF victims until a cure can be found.

enabling a cell to recognize others of its own kind. Thus, these carbohydrate chains play an important role in self-recognition and in cell-to-cell interactions, which helps cells of the same type recognize one another and form tissues. This is especially important during embryonic development. If cultures of embryonic cells of two different types, such as nerve cells and muscle cells are mixed, the cells sort themselves into separate aggregates of nerve cells and muscle cells.

2. Carbohydrate-containing surface markers are also involved in tissue growth, which is normally held within certain limits of cell density. Typically, cells do not “trespass” across the boundaries of neighbouring cells. The exception to this rule is seen in the disease of cancer (p. 489), where cancer cells, with their abnormal cell surface carbohydrate markers, spread uncontrollably, invading the space of neighbouring cells.

2.5 | Cell-to-Cell Adhesions

In multicellular organisms, such as humans, plasma membranes not only serve as the outer boundaries of all cells but also participate in cell-to-cell adhesions. These adhesions bind groups of cells together into tissues and package them further into organs. The life-sustaining activities of the body systems depend not only on the functions of the individual cells of which they are made but also on how these cells live and work together in tissue and organ communities.

Organization of cells into appropriate groupings is at least partially attributable to the carbohydrate chains on the membrane surface. Once arranged, cells are held together by three different means: (1) the extracellular matrix, (2) cell adhesion molecules in the cells' plasma membranes, and (3) specialized cell junctions.

Biological glue

Tissues are not made up solely of cells, and many cells within a tissue are not in direct physical contact with neighbouring cells. Instead, they are held together by the **extracellular matrix (ECM)**, an intricate meshwork of fibrous proteins embedded in a watery, gel-like substance composed of complex carbohydrates. The ECM serves as the biological glue. The watery gel provides a pathway for diffusion of nutrients, wastes, and other water-soluble traffic between the blood and tissue cells. It is usually called the *interstitial fluid*. Interwoven within this gel are three major types of protein fibres: collagen, elastin, and fibronectin.

1.  **Collagen** forms cable-like fibres or sheets that provide tensile strength (resistance to longitudinal stress). In *scurvy*, a condition caused by vitamin C deficiency, these fibres are not properly formed. As a result, the tissues, especially those of the skin and blood vessels, become very fragile. This leads to bleeding in the skin and mucous membranes, which is especially noticeable in the gums.
2. **Elastin** is a rubber-like protein fibre most abundant in tissues that must be capable of easily stretching and then recoiling after the stretching force is removed. It is found, for example, in the lungs, which stretch and recoil as air moves in and out.
3. **Fibronectin** promotes cell adhesion and holds cells in position. Reduced amounts of this protein have been found within certain types of cancerous tissue, possibly accounting for the fact that cancer cells do not adhere well to each other but tend to break loose and metastasize (spread elsewhere in the body).

The ECM is secreted by local cells present in the matrix. The relative amount of ECM compared with cells varies greatly among tissues. For example, the ECM is scant in epithelial tissue but is the predominant component of connective tissue. Most of this abundant matrix in connective tissue is secreted by **fibroblasts** (fibre formers). The exact composition of ECM components varies for different tissues, thus providing distinct

local environments for the various cell types in the body. In some tissues, the matrix becomes highly specialized to form such structures as cartilage or tendons or, on appropriate calcification, the hardened structures of bones and teeth.

Contrary to long-held belief, the ECM is not just passive scaffolding for cellular attachment but also helps regulate the behaviour and functions of the cells with which it interacts. Investigators have shown that cells are able to function normally and indeed even to survive only when in association with their normal matrix components. The matrix is especially influential in cell growth and differentiation. In the body, only circulating blood cells are designed to survive and function without attaching to the ECM.

Cell junctions

In tissues where the cells lie in close proximity to one another, some tissue cohesion is provided by the cell adhesion molecules (CAMs). These special loop-and-hook-shaped surface membrane proteins function like Velcro to connect adjacent cells to each other. In addition, some cells within given types of tissues are directly linked by one of the three types of specialized cell junctions: (1) desmosomes (adhering junctions), (2) tight junctions (impermeable junctions), or (3) gap junctions (communicating junctions).

DESMOSOMES

Desmosomes act like spot rivets, anchoring together two closely adjacent but nontouching cells. A desmosome consists of two components: (1) a pair of dense, button-like cytoplasmic thickenings known as *plaque*, located on the inner surface of each of the two adjacent cells; and (2) strong glycoprotein filaments containing cadherins (a type of CAM) that extend across the space between the two cells and attach to the plaque on both sides (► Figure 2-9). These intercellular filaments bind adjacent plasma membranes together so that they resist being pulled apart. Thus, desmosomes are adhering junctions.

Desmosomes are most abundant in tissues that are subject to considerable stretching, such as those found in the skin, the heart, and the uterus. In these tissues, functional groups of cells are riveted together by desmosomes that extend from one cell to the next, then from that cell to the next, and so on. Furthermore, intermediate cytoskeletal filaments, such as tough keratin filaments in the skin, stretch across the interior of these cells and attach to the desmosome plaques located on opposite sides of the cell's inner surface. This arrangement forms a continuous network of strong fibres extending throughout the tissue, both through the cells and between the cells, much like a continuous line of people firmly holding hands. This interlinking fibrous network provides tensile strength, reducing the chances of the tissue being torn when stretched.

TIGHT JUNCTIONS

At **tight junctions**, adjacent cells firmly bind with each other at points of direct contact to seal off the passageway between the two cells. They are found primarily in sheets of epithelial tissue. Epithelial tissue covers the surface of the body and lines all its

► **FIGURE 2-9 Desmosome.** Desmosomes are adhering junctions that spot-rivet cells, anchoring them together in tissues subject to considerable stretching.

internal cavities. All epithelial sheets serve as highly selective barriers between two compartments that have considerably different chemical compositions. For example, the epithelial sheet that lines the digestive tract separates the food and potent digestive juices within the inner cavity (lumen) from the blood vessels that lie on the other side. It is important that only completely digested food particles, and not undigested food particles or digestive juices, move across the epithelial sheet from the lumen to the blood. Accordingly, the lateral (side) edges of the adjacent cells in the epithelial sheet are joined in a tight seal near their luminal border by “kiss” sites, sites of direct fusion of *junctional proteins* on the outer surfaces of the two interacting plasma membranes (► Figure 2-10). These tight junctions are impermeable and thus prevent materials from passing between the cells. Passage across the epithelial barrier, therefore, must take place *through* the cells, not *between* them. This traffic across the cell is regulated by means of the channels and carriers present. If the cells were not joined by tight junctions, uncontrolled exchange of molecules could take place between the compartments by unpoliced traffic through the spaces between adjacent cells. Tight junctions thus prevent undesirable leaks within epithelial sheets.

GAP JUNCTIONS

At a **gap junction**, as the name implies, a gap exists between adjacent cells, which are linked by small, connecting tunnels formed by connexons. A **connexon** is made up of six protein subunits arranged in a hollow tube-like structure. Two connexons extend

► **FIGURE 2-10 Tight junction.** Tight junctions are impermeable junctions that join the lateral edges of epithelial cells near their luminal borders, thus preventing materials from passing between the cells. Only regulated passage of materials can occur through these cells, which form highly selective barriers that separate two compartments of highly different chemical composition.

outward, one from each of the plasma membranes of two adjacent cells, and join end to end to form the connecting tunnel between the two cells (► Figure 2-11). Gap junctions are communicating junctions. The small diameter of the tunnels permits

FIGURE 2-11 Gap junction. Gap junctions are communicating junctions consisting of small connecting tunnels made up of connexons that permit movement of charge-carrying ions and small molecules between two adjacent cells.

small, water-soluble particles to pass between the connected cells but precludes passage of large molecules, such as vital intracellular proteins. Through these specialized anatomic arrangements, ions (electrically charged particles) and small molecules can be directly exchanged between interacting cells without ever entering the ECF.

Gap junctions are especially abundant in cardiac muscle and smooth muscle. In these tissues, movement of ions between cells through gap junctions transmits electrical activity throughout an entire muscle mass. Because this electrical activity brings about contraction, the presence of gap junctions enables synchronized contraction of a whole muscle mass, such as the pumping chamber of the heart.

Gap junctions are also found in some nonmuscle tissues, where they permit unrestricted passage of small nutrient molecules between cells. For example, glucose, amino acids, and other nutrients pass through gap junctions to a developing egg cell from cells surrounding the egg within the ovary, thus helping the egg stockpile these essential nutrients.

Gap junctions also serve as avenues for the direct transfer of small signalling molecules from one cell to the next. Such transfer permits the cells connected by gap junctions to directly communicate with each other. This communication provides

one possible mechanism by which cooperative cell activity may be coordinated. In later chapters, we will continue to examine other means by which cells “talk” to each other.

Here, we now turn our attention to the topic of membrane transport, focusing on how the plasma membrane can selectively control what enters and exits the cell.

Check Your Understanding 2.3

1. Describe the structure of the plasma membrane, and explain the important roles of proteins.
2. List the three types of specialized cell junctions, and indicate their primary role.
3. Draw a desmosome.

2.6 Overview of Membrane Transport

Anything that passes between a cell and the surrounding extracellular fluid must be able to penetrate the plasma membrane. If a substance can cross the membrane, the membrane is said to be **permeable** to that substance; if a substance cannot pass, the membrane is **impermeable** to it. The plasma membrane is **selectively permeable** in that it permits some particles to pass through while excluding others.

Two properties of particles influence whether they can permeate the plasma membrane without any assistance: (1) the relative solubility of the particle in lipid, and (2) the size of the particle. Highly lipid-soluble particles can dissolve in the lipid bilayer and pass through the membrane. Uncharged or nonpolar molecules (such as O_2 , CO_2 , and fatty acids) are highly lipid soluble and readily permeate the membrane. Charged particles (ions, such as Na^+ and K^+) and polar molecules (such as glucose and proteins) have low lipid solubility but are very soluble in water. The lipid bilayer serves as an impermeable barrier to particles poorly soluble in lipid. For water-soluble (and thus lipid-insoluble) ions less than 0.8 nm in diameter, the protein channels serve as an alternative route for passage across the membrane. Only ions for which specific channels are available and open can permeate the membrane.

Particles that have low lipid solubility and are too large for channels cannot permeate the membrane on their own. Yet some of these particles must cross the membrane for the cell to survive and function. Glucose is an example of a large, poorly lipid-soluble particle that must gain entry to the cell but cannot permeate by dissolving in the lipid bilayer or passing through a channel. Cells have several means of assisted transport to move particles across the membrane that must enter or leave the cell but cannot do so unaided, as you will learn shortly.

Even if a particle can permeate the membrane by virtue of its lipid solubility or its ability to fit through a channel, some force is needed to produce its movement across the membrane. Two general types of forces are involved in accomplishing transport across the membrane: (1) forces that

do not require the cell to expend energy to produce movement (**passive forces**), and (2) forces that do require the cell to expend energy (ATP) to transport a substance across the membrane (**active forces**).

The next section describes the various methods of membrane transport, including whether each is an unassisted or assisted means of transport and whether each is a passive- or active-transport mechanism.

2.7 | Unassisted Membrane Transport

Molecules (or ions) that can penetrate the plasma membrane on their own are passively driven across the membrane by two forces: diffusion down a concentration gradient and/or movement along an electrical gradient. We first examine diffusion down a concentration gradient.

Passive diffusion of particles

At temperatures above absolute zero, all molecules (or ions) are in continuous random motion due to heat energy. This motion is most evident in liquids and gases, where the individual molecules have more room to move before colliding with another molecule. Each molecule moves separately and randomly in any direction. As a consequence of this haphazard movement, the molecules frequently collide, bouncing off each other in different directions like billiard balls striking each other. The greater the molecular concentration of a substance in a solution, the greater is the likelihood of collisions. Consequently, molecules within a particular space tend to become evenly distributed over time. Such uniform spreading out of molecules because of their random intermingling is known as **diffusion** (*diffusere* means “to spread out”). To illustrate, in ▶ Figure 2-12a, the concentration differs between area A and area B in a solution. Such a difference in concentration between two adjacent areas is called a **concentration gradient** (or **chemical gradient**). Random molecular collisions will occur more frequently in area A because of its greater concentration of molecules. For this reason, more molecules will bounce from area A into area B than in the opposite direction. In both areas, the individual molecules will move randomly and in all directions, but the net movement of molecules by diffusion will be from the area of higher concentration to the area of lower concentration.

The term **net diffusion** refers to the difference between two opposing movements. If ten molecules move from area A to area B while two molecules simultaneously move from B to A, the net diffusion is eight molecules moving from A to B. Molecules will spread in this way until the substance is uniformly distributed between the two areas and a concentration gradient no longer exists (▶ Figure 2-12b). At this point, even though movement is still taking place, no net diffusion is occurring because the opposing movements exactly counterbalance each other—that is, are in equilibrium. Movement of molecules from area A to area B will be exactly matched by movement of molecules from B to A. This situation is an example of a **steady state**.

Many different factors influence how long it takes for molecules in solution to reach steady state, the two most prominent being temperature and molecular size. Temperature is directly proportional to the speed by which molecules move in solution, meaning that at higher temperatures, the molecules move faster and reach steady state faster. In contrast, molecular movement is inversely proportional to molecular size. The larger the molecule, the slower it moves in solution and, therefore, the longer it takes to reach steady state.

What happens if a plasma membrane separates different concentrations of a substance? If the substance can permeate the membrane, net diffusion of the substance will occur through the membrane down its concentration gradient from the area of high concentration to the area of low concentration (▶ Figure 2-13a). No energy is required for this movement, so it is a passive mechanism of membrane transport. The process of diffusion is crucial to the survival of every cell and plays an important role in many specialized homeostatic activities. As an example, oxygen is transferred across the lung membrane by this means. The blood carried to the lungs is low in oxygen, having given up oxygen to the body tissues for cell metabolism. The air in the lungs, in contrast,

▶ **FIGURE 2-12 Diffusion.** (a) Diffusion down a concentration gradient. (b) Steady state, with no net diffusion occurring

► **FIGURE 2-13** Diffusion through a membrane. (a) Net diffusion across the membrane down a concentration gradient. (b) No diffusion through the membrane despite the presence of a concentration gradient

is high in oxygen because it is continuously exchanged with fresh air through the process of breathing. Because of this concentration gradient, net diffusion of oxygen occurs from the lungs into the blood as blood flows through the lungs. Thus, as blood leaves the lungs for delivery to the tissues, it is high in oxygen.

Passive diffusion of ions

The movement of ions (electrically charged particles that have either lost or gained an electron) is also affected by their electrical charge. Like charges (those with the same kind of charge) repel each other, and opposite charges attract each other. If a relative difference in charge exists between two adjacent areas, the positively charged ions (*cations*) tend to move toward the more negatively charged area, whereas the negatively charged ions (*anions*) tend to move toward the more positively charged area. A difference in charge between two adjacent areas thus produces an **electrical gradient** that promotes the movement of ions toward the area of opposite charge. The cell does not have to expend energy for ions to move into or out of the cell along an electrical gradient. This method of membrane transport is passive, similar to particles moving passively down their concentration gradient. However, only ions that can permeate the plasma membrane can move along this gradient.

When both an electrical and a concentration (chemical) gradient act simultaneously on a specific ion, the result is an **electrochemical gradient**. In Section 2.10 you will learn how electrochemical gradients contribute to the electrical properties of the plasma membrane.

Osmosis

Water can readily permeate the plasma membrane. It is small enough to slip between the phospholipid molecules within the lipid bilayer. As well, in some cell types, membrane proteins form

aquaporins, which are channels used for the passage of water (*aqua* means “water”). About a billion water molecules can pass single file through an aquaporin channel in one second. The driving force for movement of water across the membrane is the same as for any other diffusing molecule—namely, its concentration gradient. Usually the term *concentration* refers to the density of the solute (dissolved substance) in a given volume of water. It is important to recognize, however, that adding a solute to pure water in essence decreases the water concentration. In general, one molecule of a solute displaces one molecule of water.

Compare the water and solute concentrations in the two containers in ► Figure 2-14. The container in part (a) of the figure is full of pure water, so the water concentration is 100 percent and the solute concentration is 0 percent. In part (b), solute has replaced 10 percent of the water molecules. The water concentration is now 90 percent, and the solute concentration is 10 percent; this is a lower water concentration and a higher solute concentration than in part (a). Note that as the solute concentration increases, the water concentration decreases correspondingly.

If solutions of unequal solute concentration (and hence unequal water concentration) are separated by a membrane that permits passage of water, such as the plasma membrane, water will move passively down its own concentration gradient from the area of higher water concentration (lower solute concentration) to the area of lower water concentration (higher solute concentration) (► Figure 2-15). This net diffusion of water is known as **osmosis**. Because solutions are always referred to in terms of their concentration of solute, *water moves by osmosis to the*

► **FIGURE 2-14** Relationship between solute and water concentration in a solution

► **FIGURE 2-15 Osmosis.** Osmosis is the net diffusion of water down its own concentration gradient (to the area of higher solute concentration).

area of higher solute concentration. Despite the impression that the solutes are “drawing”—that is, attracting—water, osmosis is nothing more than diffusion of water down its own concentration gradient across the membrane.

The discussion of osmosis so far has ignored any movement of solute. In the following sections we consider the movement of solute and compare the results of osmosis when the solute can and cannot permeate the membrane.

OSMOSIS WHEN A MEMBRANE SEPARATES UNEQUAL SOLUTIONS OF A PENETRATING SOLUTE

Assume that solutions of unequal solute concentration are separated by a membrane that permits passage of both water and the solute. Because the membrane is permeable to the solute as well as to water, the solute can move down its own concentration gradient in the opposite direction of the net water movement (► Figure 2-16). This movement continues until both the solute and the water are evenly distributed across the membrane. With all concentration gradients gone, osmosis ceases. The final volume of the compartments when the steady state is achieved is the same as at the onset. Water and solute molecules have merely exchanged places between the two compartments until their distributions have equalized; that is, an equal number of water molecules have moved from side 1 to side 2 as solute molecules have moved from side 2 to side 1.

OSMOSIS WHEN A MEMBRANE SEPARATES UNEQUAL SOLUTIONS OF A NONPENETRATING SOLUTE

For solutions of unequal solute concentrations separated by a membrane that is permeable to water but impermeable to the solute, the solute cannot cross the membrane to move down its concentration gradient (► Figure 2-17). At first, the concentration gradients are identical to those in the previous example. However, even though net diffusion of water takes place from side 1 to side 2, the solute cannot move. As a result of water movement alone, the volume of side 2 increases while the volume of side 1 correspondingly decreases. Loss of water from side 1 increases the solute concentration on side 1, whereas addition of water to side 2 reduces the solute concentration on that

► **FIGURE 2-16 Movement of water and a penetrating solute unequally distributed across a membrane**

side. Eventually, the concentrations of water and solute on the two sides of the membrane become equal, and net diffusion of water ceases. Unlike the situation in which the solute can also permeate, diffusion of water alone has resulted in a change in the final volumes of the two compartments. The side originally containing the greater solute concentration has a larger volume, having gained water.

OSMOSIS WHEN A MEMBRANE SEPARATES PURE WATER FROM A SOLUTION OF A NONPENETRATING SOLUTE

What happens when a nonpenetrating solute is present on side 2 and pure water is present on side 1 (► Figure 2-18)? Osmosis occurs from side 1 to side 2, but the concentrations between the two compartments can never become equal. No matter how dilute side 2 becomes because of water diffusing into it, it can never become pure water, nor can side 1 ever acquire any solute. Because equilibrium is impossible to achieve, does net diffusion of water (osmosis) continue until all the water has left side 1? No. As the volume expands in compartment 2, a difference in hydrostatic pressure between the two compartments is created, and it opposes osmosis. **Hydrostatic (fluid) pressure** is the pressure exerted by a standing, or stationary, fluid on an object—in this case, the plasma membrane (*hydro* means “fluid”;

FIGURE 2-17 Osmosis in the presence of an unequally distributed nonpenetrating solute

static means “standing”). The hydrostatic pressure exerted by the larger volume of fluid on side 2 is greater than the hydrostatic pressure exerted on side 1. This hydrostatic pressure difference tends to push fluid from side 2 to side 1.

The **osmotic pressure** of a solution is a measure of the tendency for water to move into that solution because of its relative concentration of nonpenetrating solutes and water. Net movement of water continues until the opposing hydrostatic pressure exactly counterbalances the osmotic pressure. The magnitude of the osmotic pressure is equal to the magnitude of the opposing hydrostatic pressure necessary to completely stop osmosis. The greater the concentration of nonpenetrating solute and the lower the concentration of water, the greater the drive for water to move by osmosis from pure water into the solution and, therefore, the greater the opposing pressure required to stop the osmotic flow and the greater the osmotic pressure of the solution. Therefore, a solution with a high concentration of nonpenetrating solute exerts greater osmotic pressure than a solution with a lower concentration of nonpenetrating solute does.

Osmosis is the major force responsible for the net movement of water into and out of cells. Approximately 100 times the volume

FIGURE 2-18 Osmosis when pure water is separated from a solution containing a nonpenetrating solute

of water in a cell crosses the plasma membrane every second. Yet body cells normally do not experience any net gain (swelling) or loss (shrinking) of volume because the concentration of nonpenetrating solutes in the ECF is normally carefully regulated (e.g., by the kidneys; p. 560) so that the osmotic pressure in the ECF is the same as the osmotic pressure within the cells.

TONICITY

When a solution surrounds the cell, the **tonicity** of the solution is the effect the solution has on cell volume—that is, whether the cell remains the same size, swells, or shrinks. The tonicity of a solution is determined by its concentration of nonpenetrating solutes. Solutes that can penetrate the plasma membrane quickly become equally distributed between the ECF and ICF, so they do not contribute to osmotic differences. An **isotonic solution** (*iso* means “equal”) has the same concentration of nonpenetrating solutes as normal body cells do. When a cell is bathed in an isotonic solution, there is no net movement of water across the membrane, so cell volume remains constant. For this reason, the ECF is normally kept isotonic so that no net diffusion of water occurs across the plasma membranes of body cells. This is

important because cells, especially brain cells, do not function properly if they are swollen or shrunk.

Any change in the concentration of nonpenetrating solutes in the ECF produces a corresponding change in the water concentration difference across the plasma membrane. The resultant osmotic movement of water brings about changes in cell volume. The easiest way to demonstrate this phenomenon is to place red blood cells in solutions with varying concentrations of nonpenetrating solutes. Normally the plasma in which red blood cells are suspended has the same osmotic activity as the fluid inside these cells, so the cells maintain a constant volume. If red blood cells are placed in a dilute or **hypotonic solution** (*hypo* means “below”)—a solution with a below-normal concentration of nonpenetrating solutes (and therefore a higher concentration of water)—water enters the cells by osmosis. Net gain of water by the cells causes them to swell, perhaps to the point of rupturing. If, in contrast, red blood cells are placed in a concentrated or **hypertonic solution** (*hyper* means “above”)—a solution with an above-normal concentration of nonpenetrating solutes (and therefore a lower concentration of water)—the cells shrink as they lose water by osmosis. Thus, it is crucial that the concentration of nonpenetrating solutes in the ECF quickly be restored to normal should the ECF become hypotonic (as with ingesting too much water) or hypertonic (as with losing too much water through severe diarrhoea). (See pp. 611–619 for further details about the important homeostatic mechanisms that maintain the normal concentration of nonpenetrating solutes in the ECF.)

2.8 | Assisted Membrane Transport

All the kinds of transport discussed so far—diffusion down concentration gradients, movement along electrical gradients, and osmosis—produce net movement of molecules capable of permeating the plasma membrane by virtue of their lipid solubility or small size. Large, poorly lipid-soluble molecules, such as proteins, glucose, and amino acids, cannot cross the plasma membrane on their own no matter what forces are acting on them. These molecules are too big for channels, and they cannot dissolve in the lipid bilayer. This impermeability ensures that the large polar intracellular proteins cannot escape from the cell. These proteins therefore stay in the cell where they belong and can carry out their life-sustaining functions. For example, they serve as metabolic enzymes (e.g., phosphofructokinase, used in glycolysis).

However, because large, poorly lipid-soluble molecules cannot cross the plasma membrane on their own, the cell must provide mechanisms for deliberately transporting these types of molecules into or out of the cell as needed. For example, the cell must usher in essential nutrients, such as glucose for energy and amino acids for the synthesis of proteins, and transport out metabolic wastes and secretory products, such as water-soluble protein hormones. Furthermore, passive diffusion alone cannot always account for the movement of small ions. Cells use two different mechanisms of membrane transport to accomplish

these selective transport processes: (1) *carrier-mediated transport* for transfer of small, water-soluble substances across the membrane, and (2) *vesicular transport* for movement of large molecules and multimolecular particles between the ECF and ICF. We now examine each of these methods of assisted membrane transport.

Carrier-mediated transport

Carrier proteins span the thickness of the plasma membrane and can reverse shape so that specific binding sites can alternately be exposed at either side of the membrane. That is, the carrier “flip-flops” so that binding sites located in the interior of the carrier are alternately exposed to the ECF and the ICF. ▶ Figure 2-19 is a schematic representation of this **carrier-mediated transport**. As the molecule to be transported attaches to a binding site within the interior of the carrier on one side of the membrane (step 1), this binding causes the carrier to flip its shape so that the same site is now exposed to the other side of the membrane (step 2). Then, having been moved in this way from one side of the membrane to the other, the bound molecule detaches from the carrier (step 3). After the passenger detaches, the carrier reverts to its original shape (step 4).

Carrier-mediated transport systems display three important characteristics that determine the kind and amount of material that can be transferred across the membrane: *specificity*, *saturation*, and *competition*.

1. **Specificity.** Each carrier protein is specialized to transport a specific substance or, at most, a few closely related chemical compounds. For example, amino acids cannot bind to glucose carriers, although several similar amino acids may be able to use the same carrier. Cells vary in the types of carriers they have, thereby permitting transport selectivity among cells.

A number of inherited diseases involve defects in transport systems for a particular substance. *Cystinuria* (cysteine in the urine) is such a disease, involving defective cysteine carriers in the kidney membranes. This transport system normally removes cysteine from the fluid destined to become urine and returns this essential amino acid to the blood. When this carrier malfunctions, large quantities of cysteine remain in the urine, where it is relatively insoluble and tends to precipitate. This is one cause of urinary stones.

2. **Saturation.** A limited number of carrier binding sites are available within a particular plasma membrane for a specific substance. Therefore, there is a limit to the amount of a substance a carrier can transport across the membrane in a given time. This limit is known as the **transport maximum** (T_m). Until the T_m is reached, the number of carrier binding sites occupied by a substance and, accordingly, the substance’s rate of transport across the membrane are directly related to its concentration. The more substance available for transport, the more will be transported. When the T_m is reached, the carrier is saturated (all binding sites are occupied), and the rate of the substance’s transport across the membrane is maximal. Further increases in the substance’s concentration are not accompanied by corresponding increases in the rate of transport (▶ Figure 2-20).

© 2016 Cengage

► **FIGURE 2-19** Model for facilitated diffusion, a passive form of carrier-mediated transport

As an analogy, consider a ferry boat that can maximally carry 100 people across a river during one trip in an hour. If 25 people are on hand to board the ferry, 25 will be transported that hour. Doubling the number of people on hand to 50 will double the rate of transport to 50 people that hour. Such a direct relationship will exist between the number of people waiting to board (the concentration) and the rate of transport until the ferry is fully occupied (its T_m is reached). The ferry can maximally transport 100 people per hour. Even if 150 people are waiting to board, still only 100 will be transported per hour.

Saturation of carriers is a critical rate-limiting factor in the transport of selected substances across the kidney membranes during urine formation and across the intestinal membranes during absorption of digested foods. Furthermore, it is sometimes possible to regulate (e.g., by hormones) the rate of carrier-mediated transport by varying the affinity (attraction) of the binding site for its passenger or by varying the number of binding sites. For example, the hormone insulin greatly increases the carrier-mediated transport of glucose into most cells of the body by promoting an increase in the number of glucose carriers in the cell's plasma membrane.

Deficient insulin action (*diabetes mellitus*) drastically impairs the body's ability to take up and use glucose as the primary energy source.

3. Competition. Several closely related compounds may compete for a ride across the membrane on the same carrier. If a given binding site can be occupied by more than one type of molecule, the rate of transport of each substance is less when both molecules are present than when either is present by itself. To illustrate, assume the ferry has 100 seats (binding sites) that can be occupied by either men or women. If only men are waiting to board, up to 100 men can be transported during each trip; the same holds true if only women are waiting to board. If, however, both men and women are waiting to board, they will compete for the available seats so that fewer men and fewer women will be transported than when either group is present alone. Fifty of each might make the trip, although the total number of people transported will still be the same, 100 people. In other words, when a carrier can transport two closely related substances, such as the amino acids glycine and alanine, the presence of both diminishes the rate of transfer for either.

► **FIGURE 2-20** Comparison of carrier-mediated transport and simple diffusion down a concentration gradient. With simple diffusion of a molecule down its concentration gradient, the rate of transport of the molecule into the cell is directly proportional to the extracellular concentration of the molecule. With carrier-mediated transport of a molecule down its concentration gradient, the rate of transport of the molecule into the cell is directly proportional to the extracellular concentration of the molecule until the carrier is saturated, at which time the rate of transport reaches a maximum value (transport maximum, or T_m). The rate of transport does not increase with further increases in the ECF concentration of the molecule.

Active or passive transport

Carrier-mediated transport takes two forms, depending on whether energy must be supplied to complete the process: *facilitated diffusion* (not requiring energy) and *active transport* (requiring energy). **Facilitated diffusion** uses a carrier to facilitate (assist) the transfer of a particular substance across the membrane “downhill”—that is, along a concentration gradient, from high to low concentration. This process is passive and does not require energy because movement occurs naturally down a concentration gradient. The unassisted diffusion described earlier is sometimes called *simple diffusion*, to distinguish it from facilitated diffusion. **Active transport**, in contrast, requires the carrier to expend energy to transfer its passenger “uphill”—that is, against a concentration gradient, from an area of lower concentration to an area of higher concentration. An analogous situation is a car on a hill. To move the car downhill requires no energy; it will coast from the top down. Driving the car uphill, however, requires the use of energy (gasoline or electricity).

FACILITATED DIFFUSION

The most notable example of facilitated diffusion is the transport of glucose into cells. Glucose is in higher concentration in the blood than in the tissues. Fresh supplies of this nutrient are regularly added to the blood through eating and by using reserve energy stores in the body. Simultaneously, the cells metabolize glucose almost as rapidly as it enters the cells from the blood. As a result, a continuous gradient exists for net diffusion of glucose into the cells. However, glucose cannot cross cell membranes on

its own. Because glucose is polar, it is not lipid soluble and it is also too large to fit through a channel. Without the glucose-carrier molecules to facilitate membrane transport of glucose, the cells would be deprived of glucose, their preferred source of fuel.

The carrier binding sites involved in facilitated diffusion can bind with their passenger molecules when exposed to either side of the membrane (see ► Figure 2-19). Passenger binding triggers the carrier to flip its conformation and drop off the passenger on the opposite side of the membrane. Because passengers are more likely to bind with the carrier on the high-concentration side than on the low-concentration side, the net movement always proceeds down the concentration gradient from higher to lower concentration. As is characteristic of mediated transport, the rate of facilitated diffusion is limited by saturation of the carrier binding sites, unlike the rate of simple diffusion, which is always directly proportional to the concentration gradient (see ► Figure 2-20).

ACTIVE TRANSPORT

Active transport also involves the use of a protein carrier to transfer a specific substance across the membrane, but in this case the carrier transports the substance against its concentration gradient. For example, the uptake of iodine by thyroid gland cells necessitates active transport because 99 percent of the iodine in the body is concentrated in the thyroid. To move iodine from the blood, where its concentration is low, into the thyroid, where its concentration is high, requires expenditure of energy to drive the carrier. Specifically, in active transport, energy in the form of ATP is required to alter the relative affinity of the binding site when exposed on one side of the plasma membrane or to the other. By contrast, in facilitated diffusion, the affinity of the binding site is the same when exposed to either the outside or the inside of the cell.

With active transport, the binding site has a greater affinity for its passenger on the low-concentration side due to *phosphorylation* of the carrier. The carrier exhibits ATPase activity in that it splits the terminal phosphate from an ATP molecule to yield ADP plus a free inorganic phosphate. The phosphate group is then attached to the carrier. This phosphorylation and the binding of the passenger on the low-concentration side cause the carrier protein to flip its conformation so that the passenger is now exposed to the high-concentration side of the membrane. The change in carrier shape is accompanied by *dephosphorylation*; that is, the phosphate group detaches from the carrier. Removal of phosphate reduces the affinity of the binding site for the passenger, so the passenger is released on the high-concentration side. The carrier then returns to its original conformation. In this way, ATP energy is used in the phosphorylation–dephosphorylation cycle of the carrier. It alters

the affinity of the carrier's binding sites on opposite sides of the membrane so that transported particles are moved uphill from an area of low concentration to an area of higher concentration. These active-transport mechanisms are frequently called **pumps**, analogous to water pumps that require energy to lift water against the downward pull of gravity.

Let us now apply these basic principles of active transport and look at the **Na⁺–K⁺ ATPase pump** (**Na⁺–K⁺ pump** for short), a very important pump found in the plasma membrane of all cells.

This carrier transports sodium ions (Na⁺) out of the cell, concentrating them in the ECF, and picks up potassium ions (K⁺) from the outside, concentrating them in the ICF (▶ Figure 2-21). Splitting of ATP through ATPase activity and the subsequent phosphorylation of the carrier on the intracellular side increases the carrier's affinity for Na⁺ and induces a change in carrier shape, leading to the drop-off of Na⁺ on the exterior. The subsequent dephosphorylation of the carrier increases its affinity for K⁺ on the extracellular side and restores the original carrier conformation, thereby transferring K⁺ into the cytoplasm. There is not a direct exchange of Na⁺ for K⁺, however. The Na⁺–K⁺ pump moves three Na⁺ out of the cell for every two K⁺ it pumps in. (To appreciate the magnitude of active Na⁺–K⁺ pumping that takes place, consider that a single nerve cell membrane contains perhaps 1 million Na⁺–K⁺ pumps capable of transporting about 200 million ions per second.)

The Na⁺–K⁺ pump plays three important roles:

1. It establishes Na⁺ and K⁺ concentration gradients across the plasma membrane of all cells; these gradients are critically important in the ability of nerve and muscle cells to generate electrical signals essential to their functioning (this topic is discussed thoroughly in Sections 2.10–2.12).
2. It helps regulate cell volume by controlling the concentrations of solutes inside the cell, thereby minimizing osmotic effects that would induce swelling or shrinking of the cell.
3. The energy used to run the Na⁺–K⁺ pump also indirectly serves as the energy source for the cotransport of glucose and amino acids across intestinal and kidney cells. This process is known as *secondary active transport*.

SECONDARY ACTIVE TRANSPORT

Unlike most cells of the body, the intestinal and kidney cells actively transport glucose and amino acids by moving them uphill from low to high concentration. The intestinal cells transport these nutrients from inside the intestinal lumen into the blood, concentrating them in the blood until none of these molecules are left in the lumen to be lost in the feces. Similarly, the kidney cells save these nutrient molecules for the body by transporting them out of the fluid that is to become urine, moving them against a concentration gradient into the blood. However, energy is not directly supplied to the carrier in these instances. The carriers that transport glucose against its concentration gradient from the lumens of the intestine and kidneys are distinct from the glucose facilitated-diffusion carriers. The luminal

carriers in intestinal and kidney cells are **cotransport carriers** in that they have two binding sites, one for Na⁺ and one for the nutrient molecule. The Na⁺–K⁺ pumps in these cells are located in the basolateral membrane (the membrane at the base of the cell opposite the lumen and along the lateral edge of the cell below the tight junction; see ▶ Figure 2-10). More Na⁺ is present in the lumen than inside the cells because the energy-requiring Na⁺–K⁺ pump transports Na⁺ out of the cell at the basolateral membrane, keeping the intracellular Na⁺ concentration low. Because of this Na⁺ concentration difference, more Na⁺ binds to the luminal cotransport carrier when it is exposed to the outside (▶ Figure 2-22). Binding of Na⁺ to the cotransport carrier increases the carrier's affinity for its other passenger (e.g., glucose), so the carrier has a high affinity for glucose when exposed to the outside of the membrane. When both Na⁺ and glucose are bound to the carrier, it undergoes a change in shape and opens to the inside of the cell. Both Na⁺ and glucose are released to the interior: Na⁺ because of the lower intracellular Na⁺ concentration, and glucose because of the reduced affinity of the binding site on release of Na⁺.

The movement of Na⁺ into the cell by this cotransport carrier is downhill because the intracellular Na⁺ concentration is low, but the movement of glucose is uphill because glucose becomes concentrated in the cell. The released Na⁺ is quickly pumped out by the active Na⁺–K⁺ transport mechanism, keeping the level of intracellular Na⁺ low. The energy expended in this process is not directly used to run the cotransport carrier, because there is no need for phosphorylation to alter the affinity of the binding site to glucose. Instead, the establishment of an Na⁺ concentration gradient by a primary active-transport mechanism (the Na⁺–K⁺ pump) drives this secondary active-transport mechanism (Na⁺–glucose cotransport carrier) to move glucose against its concentration gradient. With **primary active transport**, energy is *directly* required to move a substance uphill. The term *active transport* without a qualifier typically means primary active transport. With **secondary active transport**, energy is required in the entire process, but it is *not directly* required to run the pump. Rather, it uses second-hand energy stored in the form of an **ion concentration gradient** (e.g., a Na⁺ gradient) to move the cotransported molecule uphill. This is very efficient, because Na⁺ must be pumped out anyway to maintain the electrical and osmotic integrity of the cell.

The glucose carried into the cell across the luminal border by secondary active transport then passively moves out of the cell across the basolateral border by facilitated diffusion down its concentration gradient and enters the blood. This facilitated diffusion is mediated by a passive carrier in the basolateral membrane identical to the one that transports glucose into other cells, but in intestinal and kidney cells it transports glucose out of the cell. The difference depends on the direction of the glucose concentration gradient. In the case of intestinal and kidney cells, glucose is in higher concentration inside the cells.

Before leaving the topic of carrier-mediated transport, think about all the activities that rely on carrier assistance. All cells depend on carriers for the uptake of glucose and amino acids,

FIGURE 2-21 Na⁺–K⁺ ATPase pump. The plasma membrane of all cells contains an active transport carrier, the Na⁺–K⁺ pump, which uses energy in the carrier's phosphorylation-dephosphorylation cycle to sequentially transport Na⁺ out of the cell and K⁺ into the cell against these ions' concentration gradients. This pump moves three Na⁺ out and two K⁺ in for each ATP split.

which serve as the major energy source and structural building blocks, respectively. Na⁺–K⁺ pumps are essential for generating cellular electrical activity and for ensuring that cells have an appropriate intracellular concentration of osmotically active

solutes. Active transport, either primary or secondary or both, is used extensively to accomplish the specialized functions of the nervous and digestive systems as well as the kidneys and all types of muscle.

1 A cotransport carrier at the luminal border simultaneously transfers glucose against a concentration gradient and Na^+ down a concentration gradient from the lumen into the cell.

2 No energy is directly used by the cotransport carrier to move glucose uphill. Instead operation of the cotransport carrier is driven by the Na^+ concentration gradient (low Na^+ in ICF compared with lumen) established by the energy-using Na^+-K^+ pump.

3 The Na^+-K^+ pump actively transports Na^+ out of the cell at the basolateral border keeping the ICF Na^+ concentration lower than the luminal concentration.

4 After entering the cell by secondary active transport, glucose is transported down its concentration gradient from the cell into the blood by facilitated diffusion, mediated by a passive glucose carrier at the basal border.

5 The Na^+-K^+ pump also actively transports K^+ into the cell, maintaining a high intracellular K^+ concentration.

FIGURE 2-22 Secondary active transport. Glucose (as well as amino acids) is transported across intestinal and kidney cells against its concentration gradient by means of secondary active transport.

Check Your Understanding 2.4

1. Draw a graph comparing simple diffusion down a concentration gradient and carrier-mediated transport.
2. Describe what causes the carrier to change shape and thereby expose binding sites to passengers on opposite sides of the membrane in facilitated diffusion, primary active transport, and secondary active transport.

Vesicular transport

Special carrier-mediated transport systems embedded in the plasma membrane can selectively transport ions and small polar molecules. But what happens in the case of large polar molecules or even multimolecular materials that must leave or enter the cell—such as during secretion of protein hormones (large polar molecules) by endocrine cells, or during ingestion

of invading bacteria (multimolecular particles) by white blood cells? These materials are unable to cross the plasma membrane, even with assistance. They are much too big for channels, and no carriers exist for them (they would not fit into a carrier molecule). These large particles are transferred between the ICF and ECF not by crossing the membrane but by being wrapped in a membrane-enclosed vesicle, a process known as **vesicular transport**. Vesicular transport requires energy expenditure by the cell, so it is an active method of membrane transport. Energy is needed to accomplish vesicle formation and vesicle movement within the cell. Transport into the cell in this manner is termed **endocytosis**, whereas transport out of the cell is called **exocytosis**.

ENDOCYTOSIS

In endocytosis, the plasma membrane surrounds the substance to be ingested, then fuses over the surface, pinching off a membrane-enclosed vesicle so that the engulfed material is trapped within the cell (Figure 2-23). There are three

(a) Pinocytosis

(b) Receptor-mediated endocytosis

Worn-out red blood cell White blood cell

(c) Phagocytosis

FIGURE 2-23 Three forms of endocytosis. (a) Diagram and electron micrograph of pinocytosis. The surface membrane dips inward to form a pouch, then seals the surface, forming an intracellular endocytic vesicle that nonselectively internalizes a bit of ECF. (b) Diagram and electron micrograph of receptor-mediated endocytosis. When a large molecule such as a protein attaches to a specific surface receptor, the membrane pockets inward with the aid of a coat protein, forming a coated pit, then pinches off to selectively internalize the molecule in an endocytic vesicle. (c) Diagram and scanning electron micrograph series of phagocytosis. White blood cells internalize multimolecular particles such as bacteria or old red blood cells by extending pseudopods that wrap around and seal in the targeted material. A lysosome fuses with and degrades the vesicle contents.

forms of endocytosis, depending on the nature of the material internalized: pinocytosis, receptor-mediated endocytosis, and phagocytosis.

Once inside the cell, an engulfed vesicle has two possible destinies:

1. In most instances, lysosomes fuse with the vesicle to degrade and release its contents into the intracellular fluid.
2. In some cells, the endocytotic vesicle bypasses the lysosomes and travels to the opposite side of the cell, where it releases its contents by exocytosis. This provides a pathway to shuttle intact particles through the cell. Such vesicular traffic is one way that materials can be transferred through the thin cells lining the capillaries, across which exchanges are made between the blood and surrounding tissues.

PINOCYTOSIS With **pinocytosis** (“cell drinking”), a small droplet of extracellular fluid is internalized. First, the plasma membrane dips inward, forming a pouch that contains a small bit of ECF (► Figure 2-23a). The endocytotic pouch is formed as a result of membrane-deforming coat proteins attaching to the inner surface of the plasma membrane. These coat proteins are similar to those involved in the formation of secretory vesicles. The linking of the coat proteins causes the plasma membrane to dip inward. The plasma membrane then seals at the surface of the pouch, trapping the contents in a small, intracellular **endocytotic vesicle**. Dynamin, a protein molecule responsible for pinching off an endocytotic vesicle, forms rings that wrap around and “wring the neck” of the pouch, severing the vesicle from the surface membrane. Besides bringing ECF into a cell, pinocytosis provides a way to retrieve extra plasma membrane that has been added to the cell surface during exocytosis.

RECEPTOR-MEDIATED ENDOCYTOSIS Unlike pinocytosis, which involves the nonselective uptake of the surrounding fluid, **receptor-mediated endocytosis** is a highly selective process that enables cells to import specific large molecules that it needs from its environment. Receptor-mediated endocytosis is triggered by the binding of a specific molecule, such as a protein, to a surface membrane receptor site specific for that protein. This binding causes the plasma membrane at that site to sink in, then seal at the surface, trapping the protein inside the cell (► Figure 2-23b). Cholesterol complexes, vitamin B12, the hormone insulin, and iron are examples of substances selectively taken into cells by receptor-mediated endocytosis.

Unfortunately, some viruses can sneak into cells by exploiting this mechanism. For instance, flu viruses and HIV, the virus that causes AIDS (p. 491) gain entry to cells via receptor-mediated endocytosis. They do so by binding with membrane receptor sites normally designed to trigger the internalization of a needed molecule.

PHAGOCYTOSIS During **phagocytosis** (“cell eating”), large multimolecular particles are internalized. Most body cells perform pinocytosis, many carry out receptor-mediated endocytosis, but only a few specialized cells are capable of phagocytosis. The latter are the “professional” phagocytes, the most notable being certain types of white blood cells that play an important role in the body’s defence mechanisms (see Chapter 11 to find

out more about immune cells). When a white blood cell encounters a large multimolecular particle, such as a bacterium or tissue debris, it extends surface projections known as **pseudopods** (false feet) that completely surround or engulf the particle and trap it within an internalized vesicle (► Figure 2-23c). A lysosome fuses with the membrane of the internalized vesicle and releases its hydrolytic enzymes into the vesicle, where they safely attack the bacterium or other trapped material without damaging the remainder of the cell. The enzymes largely break down the engulfed material into reusable raw ingredients, such as amino acids, glucose, and fatty acids that the cell can use.

EXOCYTOSIS

In exocytosis, almost the reverse of endocytosis occurs. A membrane-enclosed vesicle formed within the cell fuses with the plasma membrane, then opens up, and releases its contents to the exterior. Materials packaged for export by the endoplasmic reticulum and Golgi complex are externalized by exocytosis.

Exocytosis serves two different purposes:

1. It provides a mechanism for secreting large polar molecules, such as protein hormones and enzymes that are unable to cross the plasma membrane. In this case, the vesicular contents are highly specific and are released only on receipt of appropriate signals.
2. It enables the cell to add specific components to the membrane, such as selected carriers, channels, or receptors, depending on the cell’s needs. In such cases, the composition of the membrane surrounding the vesicle is important, and the contents may be merely a sampling of ICF.

Secretory vesicles

How does the Golgi complex sort and direct finished proteins to the proper destinations? Finished products are collected within the dilated edges of the Golgi complex’s sacs. The dilated edge of the outermost sac then pinches off to form a membrane-enclosed vesicle that contains the finished product. For each type of product to reach its appropriate site of function, each distinct type of vesicle takes up a specific product before budding off. Vesicles with their selected cargo destined for different sites are wrapped in membranes containing different surface protein molecules. Each different surface protein marker serves as a specific **docking marker** (like an address on an envelope). Each vesicle can “dock” and “unload” its cargo only at the appropriate “docking-marker acceptor,” a protein located only at the proper destination within the cell (like a house address). Thus, Golgi products are sorted and delivered like addressed envelopes containing particular pieces of mail being delivered only to the appropriate house addresses.

Specialized secretory cells include endocrine cells, which secrete protein hormones, and digestive gland cells, which secrete digestive enzymes. In secretory cells, numerous large **secretory vesicles**, which contain proteins to be secreted, bud off from the Golgi stacks. The secretory proteins remain stored within the secretory vesicles until the cell is stimulated by a specific signal that indicates a need for release of that particular secretory product. On appropriate stimulation, the vesicles move to the cell’s periphery. Vesicular contents are quickly released to

FIGURE 2-24 Exocytosis of a secretory product. A secretory vesicle fuses with the plasma membrane, releasing the vesicle contents to the cell exterior. The vesicle membrane becomes part of the plasma membrane.

the cell's exterior as the vesicle fuses with the plasma membrane, opens, and empties its contents to the outside (▶ Figure 2-24). Release of the contents of a secretory vesicle by means of exocytosis constitutes the process of secretion. Secretory vesicles fuse only with the plasma membrane and not with any of the internal

membranes associated with organelles, thereby preventing fruitless or even dangerous discharge of secretory products into the organelles.

We now examine how secretory vesicles take up specific products to be released into the ECF and then dock only at the plasma membrane. Before budding off from the outermost Golgi sac, the portion of the Golgi membrane that will be used to enclose the secretory vesicle becomes coated with a layer of specific proteins from the cytosol (▶ Figure 2-25). These and associated membrane proteins serve three important functions:

1. Specific proteins on the interior surface of the membrane facing the Golgi lumen act as *recognition markers* for the recognition and attraction of specific molecules that have been processed in the Golgi lumen. The newly finished proteins destined for secretion contain a unique sequence of amino acids known as a *sorting signal*. Recognition of the right protein's sorting signal by the complementary membrane marker ensures that the proper cargo is captured and packaged within a secretory vesicle that forms and buds off the outermost Golgi sac.
2. *Coat proteins* from the cytosol bind with another specific protein facing the outer surface of the membrane. The linking

2

KEY

- 1 Recognition markers in the membrane of the outermost Golgi sac capture the appropriate cargo from the Golgi lumen by binding only with the sorting signals of the protein molecules to be secreted. The membrane that will wrap the vesicle is coated with coatomer, which causes the membrane to curve, forming a bud.
- 2 The membrane closes beneath the bud, pinching off the secretory vesicle.
- 3 The vesicle loses its coating, exposing v-SNARE docking markers on the vesicle surface.
- 4 The v-SNAREs bind only with the t-SNARE docking-marker acceptors of the targeted plasma membrane, ensuring that secretory vesicles empty their contents to the cell's exterior.

FIGURE 2-25 Packaging, docking, and release of secretory vesicles. The diagram series illustrates secretory vesicle formation and budding, with the aid of a coat protein, and docking with the plasma membrane by means of v-SNAREs and t-SNAREs. The transmission electron micrograph shows secretion by exocytosis.

of these coat proteins causes the surface membrane of the Golgi sac to curve and form a dome-shaped bud around the captured cargo. Eventually, the surface membrane closes and pinches off the vesicle.

3. After budding off, the vesicle sheds its coat proteins. This uncoating exposes *docking markers*, which are other specific proteins facing the outer surface of the vesicle membrane. These docking markers, known as *v-SNAREs*, can link in a lock-and-key fashion with another protein marker, a *t-SNARE*, found only on the targeted membrane. In the case of secretory vesicles, the targeted membrane is the plasma membrane, the designated site for secretion to take place. In this way, the *v-SNAREs* of secretory vesicles are able to fuse only with the *t-SNAREs* of the plasma membrane. Once a vesicle has docked at the appropriate membrane by means of matching SNAREs, the two membranes completely fuse; then the vesicle opens up and empties its contents at the targeted site.

Note that the contents of secretory vesicles never come into contact with the cytosol. From the time these products are first synthesized in the endoplasmic reticulum until they are released from the cell by exocytosis, they are always wrapped in a membrane and thus isolated from the remainder of the cell. By manufacturing its particular secretory protein ahead of time and storing this product in secretory vesicles, a secretory cell has a readily available reserve from which to secrete large amounts of this product on demand (e.g., digestive hormones). If a secretory cell had to synthesize all of its product on the spot as needed for export, the cell would be more limited in its ability to meet varying levels of demand.

Secretory vesicles are formed only by secretory cells. In a similar way, however, the Golgi complex of these and other cell types sorts and packages newly synthesized products for different destinations within the cell. In each case, a particular vesicle captures a specific kind of cargo from among the many proteins in the Golgi lumen, and then addresses each shipping container for a distinct destination.

Balance of endocytosis and exocytosis

The rate of endocytosis and exocytosis is tightly regulated in order to maintain a constant membrane surface area and cell volume. More than 100 percent of the plasma membrane may be used in an hour to wrap internalized vesicles in a cell actively involved in endocytosis, and this necessitates the rapid replacement of surface membrane by exocytosis. In contrast, when a secretory cell is stimulated to secrete, it may temporarily insert up to 30 times its surface membrane through exocytosis. This added membrane must be specifically retrieved by an equivalent volume of endocytotic activity. Thus, through exocytosis and endocytosis, portions of the membrane are constantly being restored, retrieved, and generally recycled.

Our discussion of membrane transport is now complete; Table 2-3 summarizes the pathways by which materials can pass between the ECF and the ICF. Cells are differentially selective in what enters or leaves because they have varying numbers and kinds of channels, carriers, and mechanisms for vesicular transport. Large polar molecules (too large for channels and not lipid soluble) for which there are no special transport mechanisms are unable to permeate.

■ **TABLE 2-3** Characteristics of the Methods of Membrane Transport

Methods of Transport	Substances Involved	Energy Requirements and Force-Producing Movement	Limit to Transport
Diffusion			
Through lipid bilayer	Nonpolar molecules of any size (e.g., O ₂ , CO ₂ , and fatty acids)	Passive; molecules move down concentration gradient (from high to low concentration)	Continues until the gradient is abolished (steady state with no net diffusion)
Through protein channel	Specific, small ions (e.g., Na ⁺ , K ⁺ , Ca ²⁺ , and Cl ⁻)	Passive; ions move down electrochemical gradient through open channels (from high to low concentration and by attraction of ion to area of opposite charge)	Continues until there is no net movement and a steady state is established
Special case of osmosis	Water only	Passive; water moves down its own concentration gradient (water moves to area of lower water concentration, i.e., higher solute concentration)	Continues until concentration difference is abolished or until stopped by an opposing hydrostatic pressure or until cell is destroyed
Carrier-Mediated Transport			
Facilitated diffusion	Specific polar molecules for which a carrier is available (e.g., glucose)	Passive; molecules move down concentration gradient (from high to low concentration)	Displays a transport maximum (T _m); carrier can become saturated

■ **TABLE 2-3** Characteristics of the Methods of Membrane Transport (*continued*)

Primary active transport	Specific ions or polar molecules for which carriers are available (e.g., Na ⁺ , K ⁺ , and amino acids)	Active; ions move against concentration gradient (from low to high concentration); requires ATP	Displays a transport maximum; carrier can become saturated
Secondary active transport	Specific polar molecules and ions for which cotransport carriers are available (e.g., glucose, amino acids, and some ions)	Active; molecules move against concentration gradient (from low to high concentration); driven directly by ion gradient (usually Na ⁺) established by ATP-requiring primary pump	Displays a transport maximum; cotransport carrier can become saturated
Vesicular Transport			
<i>Endocytosis</i>			
Pinocytosis	Small volume of ECF fluid; also important in membrane recycling	Active; plasma membrane dips inward and pinches off at surface, forming an internalized vesicle	Control poorly understood
Receptor-mediated endocytosis	Specific, large polar molecule (e.g., protein)	Active; plasma membrane dips inward and pinches off at surface, forming an internalized vesicle	Necessitates binding to specific receptor site on membrane surface
Phagocytosis	Multimolecular particles (e.g., bacteria and cellular debris)	Active; cell extends pseudopods that surround particle, forming an internalized vesicle	Necessitates binding to specific receptor site on membrane surface
<i>Exocytosis</i>			
	Secretory products (e.g., hormones and enzymes) as well as large molecules passing through cell intact; also important in membrane recycling	Active; increase in cytosolic Ca ²⁺ induces fusion of secretory vesicle with plasma membrane; vesicle opens up and releases contents to outside	Secretion triggered by specific neural or hormonal stimuli; other controls involved in transcellular traffic and membrane recycling not known

2.9 | Intercellular Communication and Signal Transduction

Coordination of the diverse activities of cells throughout the body to accomplish life-sustaining and other desired activities depends on the ability of cells to communicate with one another.

Communication between cells

Intercellular communication takes place in the following ways (► Figure 2-26):

1. The most intimate means of intercellular communication is through gap junctions. Through these specialized anatomic arrangements, small ions and molecules are directly exchanged between interacting cells without ever entering the extracellular fluid.
2. The presence of identifying markers on the surface membrane of some cells permits them to directly link up transiently and interact with certain other cells in a specialized way. This is the means by which the phagocytes of the body's defence

system specifically recognize and selectively destroy only undesirable cells, such as cancer cells, while leaving the body's own healthy cells alone.

3. The most common means by which cells communicate with one another is indirectly through extracellular chemical messengers, of which there are four types: *paracrine*s, *neurotransmitters*, *hormones*, and *neurohormones*. In each case, a specific chemical messenger is synthesized by specialized cells to serve a designated purpose. On being released into the ECF by appropriate stimulation, these signalling agents act on other particular cells, the messenger's **target cells**, in a prescribed manner. To exert its effect, an extracellular chemical messenger must bind with target cell receptors specific for it.

The four types of chemical messengers differ in their source and the distance and means by which they get to their site of action as follows:

- **Paracrine**s are local chemical messengers whose effect is exerted only on neighbouring cells in the immediate environment of their site of secretion. Because paracrine are distributed by simple diffusion, their action is restricted to short distances. They do not gain entry to the blood in

DIRECT INTERCELLULAR COMMUNICATION

INDIRECT INTERCELLULAR COMMUNICATION VIA EXTRACELLULAR CHEMICAL MESSENGERS

Paracrine secretion

Neurotransmitter secretion

Hormonal secretion

Neurohormone secretion

FIGURE 2-26 Types of intercellular communication. Gap junctions and transient direct linkup of cells are two means of direct communication between cells. Paracines, neurotransmitters, hormones, and neurohormones are all extracellular chemical messengers that accomplish indirect communication between cells. These chemical messengers differ in their source and the distance they travel to reach their target cells.

any significant quantity because they are rapidly inactivated by locally existing enzymes. One example of a paracrine is *histamine*, which is released from a specific type of connective tissue cell during an inflammatory response within an invaded or injured tissue (p. 469). Among other things, histamine dilates (opens more widely) the blood vessels in the vicinity, which increases blood flow to the tissue. This action brings additional blood-borne combat supplies into the affected area. It is important to note that paracines must be distinguished from chemicals that influence neighbouring cells after being nonspecifically released during the course of cellular activity. For example, an increased local concentration of carbon dioxide in an exercising muscle is among the factors that promote local dilation of the blood vessels supplying the muscle, but it is not specifically released to accomplish this particular response; therefore, carbon dioxide and

similar nonspecifically released chemicals are not considered paracines.

- Neurons communicate directly with the cells they innervate (their target cells) by releasing *neurotransmitters*, which are very short-range chemical messengers, in response to electrical signals (action potentials). Like paracines, neurotransmitters diffuse from their site of release across a narrow extracellular space to act locally on only an adjoining target cell, which may be another neuron, a muscle, or a gland.
- **Hormones** are long-range chemical messengers that are specifically secreted into the blood by endocrine glands in response to an appropriate signal. The blood carries the messengers to other sites in the body, where they exert their effects on their target cells some distance away from their site of release. Only the target cells of a particular hormone

have membrane receptors for binding with this hormone. Nontarget cells are not influenced by any blood-borne hormones that reach them.

- **Neurohormones** are hormones released into the blood by *neurosecretory neurons*. Like ordinary neurons, neurosecretory neurons can respond to and conduct electrical signals. Instead of directly innervating target cells, however, a neurosecretory neuron releases its chemical messenger, a neurohormone, into the blood upon appropriate stimulation. The neurohormone is then distributed through the blood to distant target cells. Thus, like endocrine cells, neurosecretory neurons release blood-borne chemical messengers, whereas ordinary neurons secrete short-range neurotransmitters into a confined space. From now on in this textbook the general term *hormone* will tacitly include both blood-borne hormonal and neurohormonal messengers.

In every case, extracellular chemical messengers are released from a particular cell type and interact with specific target cells to bring about a desired effect in the target cells. We now turn our attention to how these chemical messengers bring about the desired cell response.

Signal transduction

The term **signal transduction** refers to the process by which incoming signals (instructions from extracellular chemical messengers) are conveyed to the target cell's interior for execution. (A *transducer* is a device that receives energy from one system and transmits it in a different form to another system. For example, a radio receives radio waves sent out from the broadcast station and transmits these signals in the form of sound waves that can be detected by your ears.) Lipid-soluble extracellular chemical messengers, such as cholesterol-derived steroid hormones, gain entry into the cell by dissolving in and passing through the lipid bilayer of the target cell's plasma membrane. These extracellular chemical messengers bind to receptors inside the target cell and initiate the desired intracellular response themselves. By contrast, extracellular chemical messengers that are water soluble cannot gain entry to the target cell because they are poorly soluble in lipid and cannot dissolve in the plasma membrane. Protein hormones delivered by the blood and neurotransmitters released from nerve endings are the major water-soluble extracellular messengers. These messengers signal the cell to perform a given response by first binding with surface membrane receptors specific for that given messenger. These receptors are specialized proteins within the plasma membrane (p. 31). The combination of an extracellular messenger and a surface membrane receptor triggers a sequence of intracellular events that ultimately controls a particular cellular activity, such as membrane transport, secretion, metabolism, or contraction.

Despite the wide range of possible responses, the binding of an extracellular messenger (the **first messenger**) to its matching receptor brings about the desired intracellular response by only two general means: (1) by opening or closing channels, or (2) by activating second-messenger systems. We now examine these important cellular events more closely.

Chemically gated channels

Some extracellular messengers accomplish the desired intracellular response by opening or closing specific chemically gated channels in the membrane, thereby regulating the movement of particular ions into or out of the cell. An example is the opening of chemically gated channels in the subsynaptic membrane of a neuron in response to the binding of a neurotransmitter. The resultant small, short-lived movement of charge-carrying ions across the membrane through these open channels generates electrical signals.

Another example is the stimulation of muscle cells to bring about contraction. This occurs when chemically gated channels in the muscle cells open in response to the binding of neurotransmitter released from the neurons supplying the muscle. (Chapter 7 on muscle physiology describes this mechanism in detail.) The control of chemically gated channels by extracellular messengers is an important regulatory mechanism in both nerve and muscle physiology.

On completion of the response, the extracellular messenger is removed from the receptor site, and the chemically gated channels close once again. The ions that moved across the membrane through opened channels to trigger the response are returned to their original location by special membrane carriers.

Second-messenger pathways

Many extracellular chemical messengers that cannot actually enter their target cells bring about the desired intracellular response by means other than the opening of chemically gated channels. These first messengers issue their orders by triggering a "Psst, pass it on" process. The binding of the first messenger to a membrane receptor serves as a signal for activating an intracellular **second messenger**. The second messenger ultimately relays the orders through a series of biochemical intermediaries to particular intracellular proteins that carry out the dictated response, such as changes in cellular metabolism or secretory activity. The intracellular pathways activated by a second messenger in response to binding of the first messenger to a surface receptor are remarkably similar among different cell types despite the diversity of ultimate responses to that signal. The variability in response depends on the specialization of the cell, not on the mechanism used.

Some neurotransmitters function through intracellular second-messenger systems. Most, but not all, neurotransmitters function by changing the conformation of chemically gated channels, thereby altering membrane permeability and ion fluxes across the postsynaptic membrane. Synapses involving these rapid responses are considered fast synapses. However, another mode of synaptic transmission used by some neurotransmitters, such as *serotonin*, involves the activation of intracellular second messengers. Synapses that lead to responses mediated by second messengers are known as slow synapses, because these responses take longer and often last longer than those accomplished by fast synapses. For example, neurotransmitter-activated second messengers may trigger long-term postsynaptic cellular changes believed to be linked to neuronal

growth and development, as well as possibly playing a role in learning and memory.

Second-messenger systems are widely used throughout the body, including being one of the key means by which most water-soluble hormones ultimately bring about their effects. Hormonal communication is discussed in Chapter 5, where we examine second-messenger systems in more detail.

2.10 | Membrane Potential

The plasma membranes of all living cells have a membrane potential; that is, they are polarized electrically. This potential allows for cellular communication in excitable cells such as nervous tissue and muscle.

Separation of opposite charges

The term **membrane potential** quite simply refers to the difference in the electrical potential between inside and outside a cell. In Sections 2.4 and 2.6, we discussed the structure of the lipid bilayer and several methods of transport that are available for moving substances across the plasma membrane. One of the main reasons these transport mechanisms take place is that the intracellular and extracellular environments are not the same. In Section 2.8, we discussed how a particular substance such as glucose moves with or against its concentration gradient, but what happens in the case of charged ions?

When there is a difference in the relative number of cations (+) and anions (−) in the ICF (inside the cell) and ECF (outside the cell), a separation of charges is created. Opposite charges tend to attract each other, whereas like charges tend to repel. Work is performed (energy expended) to separate opposite charges after they have come together. Conversely, when oppositely charged particles have been separated, the electrical force of attraction between them can be harnessed to perform work when the charges are permitted to come together again. Because separated charges have the potential to do work, a separation of charges across the membrane is called a *membrane potential*. The potential is measured in units of volts (the same unit used for electrical devices), but because the membrane potential is relatively low, the unit used is the **millivolt (mV)** (1 mV = 1/1000 volt).

This membrane voltage is very important: if you change the voltage of the membrane, ions will move across the membrane to generate an electrical current. Likewise, if a cellular response is to move ions across the membrane, this will change the voltage or membrane potential. The relationship between voltage and current is described by Ohm's law:

$$V = IR$$

Where V is voltage (potential across the plasma membrane), I is *current* (ions moving across the membrane), and R is *resistance* (intrinsic properties of the plasma membrane to resist the movement of ions). This relationship forms the basis for understanding the importance of electrical potentials in cells.

Concentration and permeability of ions

The cells of *excitable tissues*—namely, nerve and muscle cells—have the ability to produce rapid, transient changes in their membrane potential when excited. These brief fluctuations in potential serve as electrical signals. The constant membrane potential present in the cells of nonexcitable tissues and those of excitable tissues when they are at rest—that is, when they are not producing electrical signals—is known as the **resting membrane potential**. We focus first on the generation and maintenance of the resting membrane potential and then on the changes that take place in excitable tissues during electrical signalling.

The unequal distribution of key ions between the ICF and the ECF and their selective movement through the plasma membrane are responsible for the electrical properties of the membrane. The ions primarily responsible for the generation of the resting membrane potential are sodium (Na^+), potassium (K^+), and anions (A^- ; large, negatively charged intercellular proteins). Other ions (e.g., calcium, magnesium, chloride, bicarbonate, and phosphate) do not make a significant contribution to the resting membrane potential in most cells, but they do play other important roles in the body.

The concentrations and relative permeabilities of the ions critical to membrane electrical activity are compared in Table 2-4. Note that *Na^+ is in greater concentration in the extracellular fluid* and *K^+ is in much higher concentration in the intracellular fluid*. These concentration differences are maintained by the $\text{Na}^+ - \text{K}^+$ pump with the expense of energy (ATP). Because the plasma membrane is virtually impermeable to A^- , these large, negatively charged proteins are found only inside the cell. They are synthesized from amino acids transported into the cell, and remain trapped within the cell once synthesized.

In addition to the active carrier mechanism, Na^+ and K^+ can passively cross the membrane through specific protein channels. It is usually much easier for K^+ than for Na^+ to get through the membrane, because typically the membrane has many more channels open for passive K^+ movement than for passive Na^+ movement. At resting membrane potential in a nerve cell, the membrane is about 50 to 75 times as permeable to K^+ as to Na^+ .

Knowledge of the relative concentrations and permeabilities of these ions allows us to analyze the forces acting across the plasma membrane. This analysis includes the following aspects: (1) the effect that the movement of K^+ alone would have on membrane potential; (2) the effect of Na^+ alone; and (3) the situation that exists in the cells when both K^+ and Na^+ effects are taking place concurrently. Remember, throughout this discussion *the concentration gradient for K^+ is always outward* and *the concentration gradient for Na^+ is always inward*, because the $\text{Na}^+ - \text{K}^+$ pump maintains a higher concentration of K^+ inside the cell and a higher concentration of Na^+ outside the cell. Note as well that because K^+ and Na^+ are both cations (+ charges), *the electrical gradient for both of these ions is always toward the negatively charged side of the membrane*.

TABLE 2-4 Concentration and Permeability of Ions Responsible for Membrane Potential in a Resting Nerve Cell

CONCENTRATION (millimoles/litre)			
Ion	Extracellular	Intracellular	Relative Permeability
Na ⁺	150	15	1
K ⁺	5	150	50–75
A ⁻	0	65	0

EFFECT OF THE MOVEMENT OF POTASSIUM ALONE ON MEMBRANE POTENTIAL: K⁺ EQUILIBRIUM POTENTIAL

In our first hypothetical situation, we will examine the driving forces affecting the movement of K⁺ across the plasma membrane. As Table 2-4 shows, the concentration of K⁺ is higher inside the cell than outside; therefore, there is a concentration gradient that favours the movement of K⁺ out of the cell. Figure 2-27 illustrates what happens when K⁺ leaves the cell, making the inside of the cell more negative relative to the outside and thereby establishing a membrane potential. The membrane potential, however, is negative, meaning the negatively charged interior favours the movement of cations such as K⁺ to the inside of the cell. As a result, *two opposing forces would now be acting on K⁺: the concentration gradient tending to move K⁺ out of the cell, and the electrical gradient tending to move these same ions into the cell.*

Eventually, the net outward concentration gradient and the net inward electrical gradient become balanced, so there is no net movement of K⁺ across the membrane. The potential that would exist at this equilibrium is known as the **K⁺ equilibrium potential** (E_{K^+}). At this point, because of the exactly equal opposing electrical gradient, a large concentration gradient for K⁺ would still exist, but no more net movement of K⁺ would occur out of the cell. (Figure 2-27).

The membrane potential at E_{K^+} is -90 mV. By convention, the sign always designates the polarity of the excess charge on the inside of the membrane. A membrane potential of -90 mV means that the potential is of a magnitude of 90 mV, with the inside being negative relative to the outside; a $+90$ mV would have the same strength, but the inside would be more positive.

The equilibrium potential for a given ion of differing concentrations across a membrane can be calculated by means of the **Nernst equation**, as follows:

$$E = 61 \log \frac{C_o}{C_i}$$

where

E = equilibrium potential for ion in mV

61 = a constant that incorporates the universal gas constant (R), absolute temperature (T), the ion's valence (z) (when the valence is 1+, as for K⁺ and Na⁺), an electrical constant known as Faraday (F), along with the conversion of the natural logarithm ($\ln$) to the logarithm to base 10 ($\log$)

$61 = RT/zF$. For any ion with a valence other than 1+, 61 must be divided by z to calculate a Nernst potential.

C_o = concentration of the ion outside the cell in millimoles/litre (millimolars; mM)

C_i = concentration of the ion inside the cell in mM

1 The concentration gradient for K⁺ tends to move this ion out of the cell.

2 The outside of the cell becomes more positive as K⁺ moves to the outside down its concentration gradient.

3 The membrane is impermeable to the large intracellular protein anion (A⁻). The inside of the cell becomes more negative as K⁺ moves out, leaving behind A⁻.

4 The resulting electrical gradient tends to move K⁺ into the cell.

5 No further net movement of K⁺ occurs when the inward electrical gradient exactly counterbalances the outward concentration gradient. The membrane potential at this equilibrium point is the equilibrium potential for K⁺ (E_{K^+}) at -90 mV.

FIGURE 2-27 Equilibrium potential for K⁺

Given that the ECF concentration of K^+ is 5 mM and the ICF concentration is 150 mM,

$$\begin{aligned} E_{K^+} &= 61 \log \frac{5 \text{ mM}}{150 \text{ mM}} \\ &= 61 \log \frac{1}{30} \end{aligned}$$

Because the log of $\frac{1}{30} = -1.447$,

$$E_{K^+} 61 \times (-1.477) = -90 \text{ mV}$$

Because 61 is a constant, the equilibrium potential is essentially a measure of the membrane potential (i.e., the magnitude of the electrical gradient) that exactly counterbalances the concentration gradient (i.e., the ratio between the ion's concentration outside and inside the cell) that exists for the ion. Note that the larger the concentration gradient is for an ion, the greater the ion's equilibrium potential. A comparably greater opposing electrical gradient would be required to counterbalance the larger concentration gradient.

EFFECT OF MOVEMENT OF SODIUM ALONE ON MEMBRANE POTENTIAL: Na^+ EQUILIBRIUM POTENTIAL

► Figure 2-28 illustrates another hypothetical situation, this time for the movement of Na^+ alone across the membrane. In this case, the concentration gradient for Na^+ would move this ion into the cell, producing a buildup of positive charges inside of the membrane and leaving negative charges unbalanced outside—primarily in the form of chloride (Cl^-). (Na^+ and Cl^- [i.e., salt] are the predominant ECF ions.) Net inward movement would continue until equilibrium was established by the development of an opposing electrical gradient that exactly counterbalances the concentration gradient. This is the same principle as occurs with K^+ , but in the opposite direction. Given the concentrations for Na^+ , the Na^+ equilibrium potential (E_{Na^+}) would be +60 mV. In this case the inside of the cell would be positive. The

magnitude of E_{Na^+} is somewhat less than that of E_{K^+} (60 mV compared with 90 mV). Because the concentration gradient for Na^+ is not as large as that for K^+ (see Table 2-4), the opposing electrical gradient (membrane potential) for Na^+ is not as great as that for K^+ at equilibrium.

CONCURRENT POTASSIUM AND SODIUM EFFECTS ON MEMBRANE POTENTIAL

Neither K^+ nor Na^+ exists alone in the body fluids, so equilibrium potentials are not present in body cells; they exist only in hypothetical or experimental conditions. In a living cell, the concurrent effects of both K^+ and Na^+ must be taken into account. *The greater the permeability of the plasma membrane for a given ion, the greater is the tendency for that ion to drive the membrane potential toward the ion's own equilibrium potential.* Because the membrane at rest is 50 to 75 times as permeable to K^+ as to Na^+ , K^+ passes through more readily than Na^+ ; thus, K^+ influences the resting membrane potential to a much greater extent than Na^+ does. Recall that K^+ acting alone would establish an equilibrium potential of -90 mV. However, because membrane is somewhat permeable to Na^+ , some Na^+ enters the cell in a limited attempt to reach its equilibrium potential. This neutralizes some of the membrane potential produced by K^+ alone.

To better understand this concept, assume that each separated pair of charges in ► Figure 2-29 represents 10 mV of potential. (Technically this is incorrect, because in reality many separated charges must be present to account for a potential of 10 mV.) In this simplified example, nine separated pluses and minuses, with the minuses on the inside, would represent the E_{K^+} of -90 mV. Superimposing the slight influence of Na^+ on this K^+ -dominated membrane, assume that two sodium ions enter the cell down the Na^+ concentration and electrical gradients. (Note that the electrical gradient for Na^+ is now inward, in contrast to the outward electrical gradient for Na^+ at E_{Na^+} . At E_{Na^+} , the inside of the cell is positive as a result of the inward movement of Na^+ down its concentration gradient. In a resting nerve cell, however,

► FIGURE 2-28 Equilibrium potential for Na^+

1 The Na^+/K^+ pump actively transports Na^+ out of and K^+ into the cell, keeping the concentration of Na^+ high in the ECF and the concentration of K^+ high in the ICF.

2 Given the concentration gradients that exist across the plasma membrane, K^+ tends to drive membrane potential to the equilibrium potential for K^+ (-90 mV), whereas Na^+ tends to drive membrane potential to the equilibrium potential for Na^+ ($+60\text{ mV}$).

3 However, K^+ exerts the dominant effect on resting membrane potential because the membrane is more permeable to K^+ . As a result, resting potential (-70 mV) is much closer to E_{K^+} than to E_{Na^+} .

4 During the establishment of resting potential, the relatively large net diffusion of K^+ outward does not produce a potential of -90 mV because the resting membrane is slightly permeable to Na^+ and the relatively small net diffusion of Na^+ inward neutralizes (in grey shading) some of the potential that would be created by K^+ alone, bringing resting potential to -70 mV , slightly less than E_{K^+} .

5 The negatively charged intracellular proteins (A^-) that cannot cross the membrane remain unbalanced inside the cell during the net outward movement of the positively charged ions, so the inside of the cell is more negative than the outside.

FIGURE 2-29 Effect of concurrent K^+ and Na^+ movement on establishing the resting membrane potential

the inside is negative because of the dominant influence of K^+ on membrane potential. Thus, both the concentration and the electrical gradients now favour the inward movement of Na^+ .) The inward movement of these two positively charged sodium ions neutralizes some of the potential established by K^+ , so now only seven pairs of charges are separated, and the potential is -70 mV . This is the *resting membrane potential* of a typical nerve cell. The resting potential is much closer to E_{K^+} than to E_{Na^+} because of the greater permeability of the membrane to K^+ , but it is slightly less than E_{K^+} (-70 mV is a lower potential than -90 mV) because of the weak influence of Na^+ .

CHLORIDE MOVEMENT AT RESTING MEMBRANE POTENTIAL

The Cl^- ion, present in high concentrations in the ECF, is the principal ECF anion. Its equilibrium potential is -70 mV , exactly the same as the resting membrane potential. Movement alone of negatively charged Cl^- into the cell down its concentration gradient would produce an opposing electrical gradient, with the inside negative compared with the outside. When physiologists were first examining the ionic effects that could account for the membrane potential, they were tempted to think that Cl^- movements and establishment of the Cl^- equilibrium potential could be solely responsible for producing the identical resting membrane potential. Actually, the reverse is the case. The membrane potential is responsible for driving the distribution of Cl^- across the membrane.

Most cells are highly permeable to Cl^- but have no active-transport mechanisms (no pumps) for this ion. With no active forces acting on it, Cl^- passively distributes itself to achieve an individual state of equilibrium. In this case, Cl^- is driven out

of the cell, establishing an inward concentration gradient that exactly counterbalances the outward electrical gradient (i.e., the resting membrane potential) produced by K^+ and Na^+ movement. This means the concentration difference for Cl^- between the ECF and the ICF is brought about passively by the presence of the membrane potential rather than maintained by an active pump, as is the case for K^+ and Na^+ . Therefore, in most cells Cl^- does not influence resting membrane potential; instead, membrane potential passively influences the Cl^- distribution. (Some specialized cells have an active Cl^- pump, with subsequent movement of Cl^- accounting for part of the potential.)

Specialized use of membrane potential in nerve and muscle cells

Two types of cells—nerve cells and muscle cells—have developed a specialized use for membrane potential. These cells can rapidly and transiently alter their membrane permeabilities to specific ions in response to appropriate stimulation, bringing about fluctuations in membrane potential. These fluctuations in potential serve as electrical signals. The constant membrane potential that exists when a nerve or muscle cell is not displaying rapid changes in potential is referred to as the *resting potential*. All cells display a membrane potential, but the significance of this in other cells is uncertain. For example, the membrane potential of some secretory cells appears to be linked to the level of their secretory activity.

Nerve and muscle are considered **excitable tissues** because, when excited, they change their resting potential to produce electrical signals. Nerve cells, or *neurons*, use these electrical

Upward deflection = Decrease in potential
Downward deflection = Increase in potential

© 2016 Cengage

► FIGURE 2-30 Types of changes in membrane potential

signals to receive, process, initiate, and transmit messages—that is, to communicate. In muscle cells, these electrical signals initiate muscular contraction, which is responsible for the movement involved in work and exercise. Consequently, electrical signals are critical to the function of the nervous system and all muscles. In the following section, we consider how neurons undergo changes in potential to accomplish their function. The functioning of muscle cells is discussed in Chapter 7.

Depolarization and hyperpolarization

To help you understand the nature of electrical signals and how they are created, become familiar with the terms used to describe changes in potential: polarization, depolarization, repolarization, and hyperpolarization. (► Figure 2-30 represents these terms graphically.)

1. **Polarization.** Charges are separated across the plasma membrane, so the membrane has potential. Any time the value of the membrane potential is other than 0 mV, in either a positive or a negative direction, the membrane is in a state of polarization. Recall that the magnitude of the potential is directly proportional to the number of positive and negative charges separated by the membrane and that the sign of the potential (+ or −) always designates whether excess positive or excess negative charges are present, respectively, on the inside of the membrane. At resting potential, the membrane is polarized at −70 mV in a typical neuron.
2. **Depolarization.** The resting potential becomes less negative (e.g., a change from −70 to −60 mV), and fewer charges are separated than at resting potential. So depolarization is a movement in the positive (+) direction, or upward on a recording device.
3. **Repolarization.** The membrane returns to resting potential after having been depolarized. So repolarization is a movement in the negative (−) direction, or downward on a recording device.
4. **Hyperpolarization.** The membrane becomes more polarized than at resting potential. During hyperpolarization the membrane potential moves even farther from 0 mV, becoming

more negative (for instance, a change from −70 to −80 mV); this means more charges are separated than at resting potential. Again, hyperpolarization is a movement in the negative (−) direction, or downward on the recording device.

One possibly confusing point should be clarified. On the device used for recording rapid changes in potential, a depolarization—when the inside becomes less negative than at resting potential—is represented as an *upward* deflection. By contrast, during a hyperpolarization—when the inside becomes more negative than at resting potential—is represented by a *downward* deflection.

Electrical signals and ion movement

Changes in membrane potential are brought about by changes in ion movement across the membrane. For example, if the net inward flow of positively charged ions increases compared with the resting state, the membrane becomes depolarized (less negative inside). By contrast, if the net outward flow of positively charged ions increases compared with the resting state, the membrane becomes hyperpolarized (more negative inside).

Changes in ion movement, in turn, are brought about by changes in membrane permeability in response to *triggering events*. Depending on the type of electrical signal, a triggering event might be (1) a change in the electrical field in the vicinity of an excitable membrane; (2) an interaction of a chemical messenger with a surface receptor on a nerve or muscle cell membrane; (3) a stimulus, such as sound waves stimulating specialized nerve cells in the ear; or (4) a spontaneous change of potential caused by inherent imbalances in the leak–pump cycle. (You will learn more about the nature of these triggering events as our discussion of electrical signals continues.)

Because the water-soluble ions responsible for carrying charge cannot penetrate the plasma membrane's lipid bilayer, these charges can cross the membrane only through channels specific to them. Membrane channels may be either *leak channels* or *gated channels*. **Leak channels** are open all the time, thereby permitting unregulated leakage of their chosen ion across the membrane through the channels. **Gated channels**, in contrast, have gates that can alternately be open, permitting ion passage through the channels, or closed, preventing ion passage through the channels. The opening-and-closing of gates results from a change in the three-dimensional conformation (shape) of the protein that forms the gated channel. There are four kinds of gated channels, depending on the factor that induces the change in channel conformation: (1) **voltage-gated channels**, which open or close in response to changes in membrane potential; (2) **chemically gated channels**, which change conformation in response to the binding of a specific chemical messenger to a membrane receptor in close association with the channel; (3) **mechanically gated channels**, which respond to stretching or other mechanical deformation; and (4) **thermally gated channels**, which respond to local changes in temperature (heat or cold).

Thus, triggering events alter membrane permeability and consequently alter ion flow across the membrane by opening or closing the gates guarding particular ion channels. These ion

movements redistribute charge across the membrane, causing membrane potential to fluctuate.

There are two basic forms of electrical signals: (1) *graded potentials*, which serve as short-distance signals; and (2) *action potentials*, which signal over long distances. Before we explore how nerve cells use these signals to convey messages, we will examine these types of signals in more detail, beginning with graded potentials.

1. Explain why the resting membrane potential of a cell is closer to the K^+ equilibrium potential.
2. Draw a graph depicting the changes in potential during depolarization, repolarization, and hyperpolarization as compared to resting membrane potential.
3. State the factor responsible for triggering gate opening.

2.11 | Graded Potentials

Graded potentials are local changes in membrane potential that occur in varying grades or degrees of magnitude or strength. For example, membrane potential could change from -70 to -60 mV (a 10 mV graded potential) or from -70 to -50 mV (a 20 mV graded potential).

Triggering events

Graded potentials are usually produced by a specific triggering event that causes gated ion channels to open in a specialized region of the excitable cell membrane. In most cases, these are chemically gated or mechanically gated channels. Most commonly, gated Na^+ channels open. When Na^+ channels open, Na^+ permeability increases as Na^+ moves down its concentration and electrical gradients. As a result, the membrane potential moves toward the Na^+ equilibrium potential. The resultant depolarization—the graded potential—is confined to this small, specialized region of the total plasma membrane.

The magnitude of this initial graded potential (i.e., the difference between the new potential and the resting potential) is related to the magnitude of the triggering event: *The stronger the triggering event, the more gated channels that open, the greater the positive charge entering the cell, and the larger the depolarizing graded potential at the point of origin. Also, the longer the duration of the triggering event, the longer the duration of the graded potential* (► Figure 2-31).

Graded potentials and passive currents

When a graded potential occurs locally in a nerve or muscle cell membrane, the remainder of the membrane is still at resting potential. The temporarily depolarized region is called an *active area*. Note from

► Figure 2-32 that inside the cell, the active area is relatively more positive than the neighbouring *inactive areas* that are still at resting potential. Outside the cell, the active area is relatively less positive than these adjacent areas. Because of this difference in electrical charges, passive flow between the active and adjacent resting regions on both the inside and the outside of the membrane begins. Any flow of electrical charges is called a **current**. By convention, the direction of current flow is always designated by the direction in which the positive charges are moving (► Figure 2-32b). On the inside, positive charges flow through the ICF away from the relatively more positive depolarized active region toward the more negative adjacent resting regions. Outside the cell, positive charges flow through the ECF from the more positive adjacent inactive regions toward the relatively more negative active region. Ion movement (i.e., current) is occurring *along* the membrane between regions next to each other on the same side of the membrane. This flow is in contrast to ion movement *across* the membrane through ion channels.

As a result of local current flow between an active depolarized area and an adjacent inactive area, the potential changes in the previously inactive area. Positive charges have flowed into this adjacent area on the inside, while simultaneously the positive charges have flowed out of this area on the outside. Thus, at this adjacent site the inside is more positive (or less negative), and the outside is less positive (or more negative) than before (► Figure 2-32c). Stated differently, the previously inactive adjacent region has been depolarized, so the graded potential has spread. This area's potential now differs from that of the inactive region immediately next to it on the other side, inducing further current flow at this new site, and so on. In this manner, current spreads in both directions away from the initial site of the potential change.

The amount of current that flows between two areas depends on the difference in potential between the areas and on the resistance of the material through which the charges are moving.

► **FIGURE 2-31** The magnitude and duration of a graded potential. The magnitude and duration of a graded potential depend directly on the strength and duration of the triggering event, such as a stimulus.

► **FIGURE 2-32 Current flow during a graded potential.** (a) The membrane of an excitable cell at resting potential. (b) A triggering event opens Na^+ channels, leading to the Na^+ entry that brings about depolarization. Note that the depolarization takes place at the Na^+ channel and not just anywhere along the membrane. The adjacent inactive areas are still at resting potential. (c) Local current flow occurs between the active and the adjacent inactive areas. This local current flow results in depolarization of the previously inactive areas. In this way, the depolarization spreads away from its point of origin.

Resistance is the hindrance to electrical charge movement. The greater the difference in potential, the greater is the current flow; and the lower the resistance, the greater the current flow. *Conductors* have low resistance, providing little hindrance to current flow. Electrical wires and the ICF and ECF are all good conductors, so current readily flows through them. *Insulators* have high resistance and greatly hinder movement of charge. The plastic surrounding electrical wires has high resistance, as do body lipids. As a result, current does not freely flow across the plasma membrane's lipid bilayer. Current, carried by ions, can move across the membrane only through ion channels.

Graded potentials and current loss

The passive current flow between active and adjacent inactive areas is similar to the means by which current is carried through electrical wires. We know from experience that people can get an electric shock if they touch a bare wire. This danger is due to the fact that current leaks from an electrical wire, unless it is covered with an insulating material, such as plastic. Likewise, current is lost across the plasma membrane as charge-carrying ions leak through “uninsulated” parts of the membrane—that is, through open channels. Because of this current loss, the magnitude of

► **FIGURE 2-33** Current loss across the plasma membrane. Leakage of charge-carrying ions across the plasma membrane results in progressive loss of current with increasing distance from the initial site of potential change.

the local current progressively diminishes with increasing distance from the initial site of origin (► Figure 2-33). Thus, the magnitude of the graded potential continues to decrease the farther it moves away from the initial active area. Another way of saying this is that the spread of a graded potential is *decremental* (gradually decreases). Note that in ► Figure 2-33 the magnitude of the initial change in potential is 15 mV (a change from -70 to -55 mV), which decreases as it moves along the membrane to a change in potential of 10 mV (from -70 to -60 mV) and continues to diminish the farther it moves away from the initial active area, until there is no longer a change in potential. In this way, these local currents die out within a few millimetres from the initial site of change in potential and consequently can function as signals for only very short distances.

Graded potentials have limited signalling distance, but they are critically important to the body's function, as explained in this and later chapters. The following are all graded potentials: *postsynaptic potentials*, *receptor potentials*, *end-plate potentials*, *pacemaker potentials*, and *slow-wave potentials*. Although these terms may be unfamiliar now, you will become acquainted with them as we continue discussing nerve and muscle physiology. For now, this list simply introduces the many different types of graded potentials. Excitable cells usually produce one of these types of graded potentials in response to a triggering event. In turn, graded potentials can initiate *action potentials*, the long-distance signals, in an excitable cell.

2.12 | Action Potentials

Action potentials are brief, rapid, large changes in membrane potential during which the potential actually reverses, so that the inside of the excitable cell transiently becomes more positive than the outside. Like graded potentials, a single action potential involves only a small portion of the total excitable cell membrane. However, unlike graded potentials, action potentials are conducted, or propagated, throughout the entire membrane in *nondecremental* fashion—that is, they do not diminish in

strength as they travel from their site of initiation throughout the remainder of the cell membrane. Thus, action potentials can serve as faithful long-distance signals. Think about the nerve cell that brings about the contraction of muscle cells in your big toe. If you want to wiggle your big toe, commands are sent from your brain down your spinal cord to initiate an action potential at the beginning of this nerve cell, which is located in the spinal cord. This action potential travels, undiminished, all the way down the nerve cell's long axon, which runs through your leg and terminates in your big toe muscle cells. The signal does not weaken, but instead maintains its full strength from initiation in the spinal cord to muscle contraction of the toe.

Before we look at how action potentials spread throughout the cell in an undiminishing fashion, let's first consider the changes in potential during an action potential and the permeability and ion movements responsible for generating this change in potential.

Reversal of membrane potential

If they have sufficient magnitude, graded potential changes can initiate an action potential before the graded change dies off. Typically, the portion of the excitable membrane where graded potentials are produced in response to a triggering event does not undergo action potentials. Instead, the graded potential, by electrical or chemical means, brings about depolarization of adjacent portions of the membrane where action potentials can take place.

To initiate an action potential, a triggering event causes the membrane to depolarize from the resting potential of -70 mV (► Figure 2-34). Depolarization proceeds slowly at first, until it reaches a critical level known as **threshold potential**, typically between -50 and -55 mV. At threshold potential, an explosive depolarization takes place. A recording of the membrane

► **FIGURE 2-34** Changes in membrane potential during an action potential

potential at this time shows a sharp upward deflection to +30 mV; this coincides with the rapid reversal of the membrane potential, causing the inside of the cell to become positive compared to the outside. Just as rapidly, the membrane repolarizes, dropping back to resting potential. Often the forces that repolarize the membrane push the potential too far, causing a brief phase known as **after hyperpolarization**, during which the inside of the membrane briefly becomes even more negative than normal (e.g., -80 mV) before the resting potential is restored.

The entire rapid change in potential from threshold to peak and then back to resting is called the *action potential*. Unlike the variable duration of a graded potential, the duration of an action potential is always the same in a given excitable cell. In a nerve cell, an action potential lasts for only 1 millisecond (0.001 sec), but it lasts longer in muscle, with the duration depending on the muscle type. The portion of the action potential during which the potential is reversed (between 0 and +30 mV) is called the **overshoot**. Often an action potential is referred to as a **spike**, because of its spike-like recorded appearance. Alternatively, when an excitable membrane is triggered to undergo an action potential, it is said to **fire**. Thus, the terms *action potential*, *spike*, and *firing* all refer to the same phenomenon of rapid reversal of membrane potential. If threshold potential is not reached by the initial triggered depolarization, no action potential takes place. Therefore, threshold is a critical all-or-none point. Either the membrane is depolarized to threshold and an action potential takes place, or threshold is not reached in response to the depolarizing event, and no action potential occurs (all-or-none).

Changes in membrane permeability

How is the membrane potential, which is usually maintained at a constant resting level, thrown out of balance to such an extent as to produce an action potential? Recall that K^+ makes the greatest contribution to the establishment of the resting potential, because the membrane at rest is considerably more permeable to K^+ than to Na^+ (p. 54). During an action potential, marked changes in membrane permeability to Na^+ and K^+ take place, permitting rapid fluxes of these ions down their electrochemical gradients. These ion movements carry the current responsible for the potential changes that occur during an action potential. Action potentials take place as a result of the triggered opening and subsequent closing of two specific types of channels: voltage-gated Na^+ channels and voltage-gated K^+ channels.

Through a series of five experiments conducted by Alan Lloyd Hodgkin and Andrew Fielding Huxley in 1952, the rules that govern the movement of ions in a nerve cell resulting in the generation of an action potential were determined. In essence, their papers explained the initiation and propagation of an action potential within a nerve cell. In 1963, Hodgkin and Huxley were awarded a Nobel Prize in Physiology or Medicine for the Hodgkin-Huxley model, as it was known. The references for their five papers are as follows:

VOLTAGE-GATED Na^+ AND K^+ CHANNELS

Voltage-gated membrane channels consist of proteins that have a number of charged groups. The electrical field (potential) surrounding the channels can exert a distorting force on the channel structure because charged portions of the channel proteins are electrically attracted or repelled by charges in the fluids surrounding the membrane. Unlike the majority of membrane proteins, which remain stable despite fluctuations in membrane potential, the voltage-gated channel proteins are especially sensitive to voltage changes. Small distortions in channel shape induced by changes in potential can cause them to flip to another conformation—an example of how subtle changes in structure can profoundly influence function.

The voltage-gated Na^+ channel has two gates: an *activation gate* and an *inactivation gate* (► Figure 2-35). The activation gate guards the channel by opening and closing like a hinged door. The inactivation gate consists of a ball-and-chain-like sequence of amino acids. This gate is open when the ball is dangling free on its chain and closed when the ball binds to its receptor located at the channel opening, thus blocking the opening. Both gates must be open to permit passage of Na^+ through the channel, and closure of either gate prevents passage. This voltage-gated Na^+ channel can exist in three different conformations: (1) *closed but capable of opening* (activation gate closed, inactivation gate open; ► Figure 2-35a); (2) *open, or activated* (both gates open; ► Figure 2-35b); and (3) *closed and not capable of opening, or inactivated* (activation gate open, inactivation gate closed; ► Figure 2-35c). It is the membrane

► FIGURE 2-35 Conformations of voltage-gated sodium channels

potential that determines which conformation the channel is in, which is why these are called voltage-gated channels.

Voltage-gated K^+ channels are similar to voltage-gated Na^+ channels in that they can exist in three conformations (open, closed, and inactivated); however, because most voltage-gated K^+ channels consist of four individual subunits, there are no distinct activation and inactivation gates. Rather, the influence of the electrical field changes the conformation of the subunits, which determines whether K^+ may flow through the channel.

CHANGES IN PERMEABILITY AND ION MOVEMENT DURING AN ACTION POTENTIAL

At resting potential (-70 mV), all the voltage-gated Na^+ and K^+ channels are closed. Specifically, the Na^+ channels' activation gates are closed and their inactivation gates are open—that is, the voltage-gated Na^+ channels are in their “closed-but-capable-of-opening” conformation. Therefore, passage of Na^+ and K^+ does not occur through these voltage-gated channels at resting potential. However, due to the presence of many K^+ leak channels and very few Na^+ leak channels, the resting membrane is 50 to 75 times as permeable to K^+ as to Na^+ .

When a membrane starts to depolarize toward threshold as a result of a triggering event, the activation gates of some of its voltage-gated Na^+ channels open. Because both the concentration and electrical gradients for Na^+ favour its movement into the cell, Na^+ starts to move in. The inward movement of positively charged Na^+ depolarizes the membrane further, thereby opening even more voltage-gated Na^+ channels and allowing more Na^+ to enter, and so on, in a positive-feedback cycle (▶ Figure 2-36).

This opening of channels leads to an explosive increase in Na^+ permeability (P_{Na^+}); the membrane swiftly becomes 600

times as permeable to Na^+ as to K^+ . Na^+ rushes into the cell, rapidly eliminating the internal negativity and even making the inside of the cell more positive than the outside in an attempt to drive the membrane potential to the Na^+ equilibrium potential (which is $+60$ mV; see p. 56) (▶ Figure 2-37). The potential reaches $+30$ mV, close to the Na^+ equilibrium potential. The potential does not become any more positive, because, at the peak of the action potential, the Na^+ channels start to close and inactivate, and P_{Na^+} starts to fall to its low resting value.

What causes the Na^+ channels to close? When the membrane potential reaches threshold, two closely related events take place in the gates of each Na^+ channel. First, the activation gates are triggered to *open rapidly* in response to the depolarization, converting the channel to its open (activated) conformation (see ▶ Figure 2-35b). Surprisingly, this channel opening initiates the process of channel closing. The conformational change that opens the channel also allows the inactivation gate's ball to bind to its receptor at the channel opening, thereby physically blocking the mouth of the channel. However, this closure process takes time, so the inactivation gate *closes slowly* compared with the rapidity of channel opening. Meanwhile, during the 0.5 millisecond delay after the activation gate opens and before the inactivation gate closes, both gates are open and Na^+ rushes into the cell through these open channels, bringing the action potential to its peak. Then the inactivation gate closes, membrane permeability to Na^+ plummets to its low resting value, and further Na^+ entry is prevented. The channel remains in this inactivated conformation until the membrane potential has been restored to its resting value.

Simultaneous with the inactivation of Na^+ channels, the voltage-gated K^+ channels start to slowly open at the peak of the action potential. Opening of the K^+ channel gate is a delayed voltage-gated response triggered by the initial depolarization to threshold. Thus, three action potential-related events occur at

threshold: (1) the rapid opening of the Na^+ activation gates, which permits Na^+ to enter, moving the potential from threshold to its positive peak; (2) the slow closing of the Na^+ inactivation gates, which halts further Na^+ entry after a brief time delay, keeping the potential from rising any further; and (3) the slow opening of the K^+ gates, which is in large part responsible for the potential plummeting from its peak back to resting potential. At this stage in the action potential, the membrane potential returns to resting potential after closure of the Na^+ channels, and K^+ continues to leak out, but no more Na^+ can enter. Furthermore, the return to resting potential is hastened by the opening of K^+ gates at the peak of the action potential. Opening of the voltage-gated K^+ channels greatly increases K^+ permeability (P_{K^+}) to about 300 times the resting P_{Na^+} .

This marked increase in P_{K^+} causes K^+ to rush out of the cell down its concentration and electrical gradients, carrying positive charges back to the outside. Note that at the peak of the action potential, the positive potential inside the cell tends to repel the positive K^+ ions, so the electrical gradient for K^+ is outward, unlike at resting potential. The outward movement of K^+ rapidly restores the negative resting potential.

To review (► Figure 2-37), *the rising phase of the action potential* (from threshold to +30 mV) is due to Na^+ influx (Na^+ entering the cell) induced by an explosive increase in P_{Na^+} at threshold. The *falling phase* (from +30 mV to resting potential) is brought about largely by K^+ efflux (K^+ leaving the cell), which is caused by the marked increase in P_{K^+} occurring simultaneously with the inactivation of the Na^+ channels at the peak of the neuronal action potential.

As the potential returns to resting, the changing voltage shifts the Na^+ channels to their closed-but-capable-of-opening conformation: that is, activation gate closed and the inactivation gate open. Now the channel is reset, ready to respond to another triggering event. The newly opened voltage-gated K^+ channels also close, so the membrane returns to the resting number of open K^+ leak channels. Typically, the voltage-gated K^+ channels are slow to close. As a result of this persistent increased permeability to K^+ , more K^+ may leave than is necessary to bring the potential to resting. This slight excessive K^+ efflux makes the interior of the cell transiently even more negative than resting potential, causing an after hyperpolarization.

Restoration of concentration gradient

At the completion of an action potential, the membrane potential has been restored to its resting condition, but the ion distribution has been altered slightly. Sodium has entered the cell during the rising phase, and a comparable amount of K^+ has left during the falling phase. The $\text{Na}^+ - \text{K}^+$ pump restores these ions to their original locations in the long run, but not after each action potential.

The active pumping process takes much longer to restore Na^+ and K^+ to their original locations than it takes for the passive fluxes of these ions during an action potential. However, the membrane does not need to wait until the $\text{Na}^+ - \text{K}^+$ pump slowly restores the concentration gradients before it can undergo another action potential. Actually, the movement of relatively few of the total number of Na^+ and K^+ ions present causes the large swings in potential that occur during an action potential.

Only about 1 out of 100 000 K^+ ions present in the cell leaves during an action potential, while a comparable number of Na^+ ions enters from the ECF. The movement of this extremely small proportion of the total Na^+ and K^+ during a single action potential produces dramatic 100 mV changes in potential (between -70 and +30 mV) but only infinitesimal changes in the ICF and ECF concentrations of these ions. Much more K^+ is still inside the cell than outside, and Na^+ is still predominantly an extracellular cation. Consequently, the Na^+ and K^+ concentration gradients continue to exist, and repeated action potentials can occur without the pump having to keep pace to restore the gradients.

Were it not for the pump, of course, even tiny fluxes accompanying repeated action potentials would eventually cause what is known as rundown of the concentration gradients, making further action potentials impossible. If the concentrations of Na^+ and K^+ were equal between the ECF and the ICF, changes in permeability to these ions would not bring about ion fluxes, so no change in potential would occur. Thus, the $\text{Na}^+ - \text{K}^+$ pump is critical to maintaining the concentration gradients in the long run. However, it does not have to perform its role between action potentials, nor is it directly involved in the ion fluxes or potential changes that occur during an action potential.

Check Your Understanding 2.6

1. Describe the relative contributions of K^+ and Na^+ to the resting membrane potential.
2. Outline the changes in ion fluxes that underlie the neuronal action potential.

Propagation of action potential

A single action potential involves only a small patch of the total surface membrane of an excitable cell. But if action potentials are to serve as long-distance signals, they cannot be merely isolated events occurring in a limited area of a nerve or muscle cell membrane. Mechanisms must exist to conduct or spread the action potential throughout the entire cell membrane. Furthermore, the signal must be transmitted from one cell to the next cell (e.g., along specific nerve pathways). We explain these mechanisms in three stages: first, by briefly describing neuronal structure; second, by examining how an action potential (nerve impulse) is conducted throughout a nerve cell; and third, by describing how the signal is passed to another cell.

A single nerve cell, or **neuron**, typically consists of three basic parts: the *cell body*, the *dendrites*, and the *axon*—although there are variations in structure, depending on the location and function of the neuron. The nucleus and organelles are contained in the **cell body**, or **soma**. Numerous projections called *dendrites* protrude from the cell body; in some cases up to 400 000 dendrites are located on a single cell body. These dendrites are sometimes called the *dendritic tree*, because of their shape. The dendrites receive signals from other nerve cells (► Figure 2-38). In most cases, the cell body and dendrites have many protein receptors for binding the chemical messengers from other nerve cells. Together, the cell body and dendrites constitute the *input*

FIGURE 2-38 Anatomy of the most abundant structural type of neuron (nerve cell). (a) Most, but not all, neurons consist of the basic parts represented in this figure. (b) An electron micrograph highlighting the cell body, dendrites, and part of the axon of this type of neuron within the central nervous system

zone for the nerve cell. This is the region where graded potentials are produced in response to triggering events: in this case, incoming chemical messengers.

The **axon**, or **nerve fibre**, is a single, elongated, tubular extension that conducts action potentials *away from* the cell body and eventually terminates at other cells. The axon can extend tens, hundreds, or even tens of thousands of times the diameter of the cell body in length (μm to m in length). For example, the axon of the nerve cell innervating your big toe must traverse the distance from the origin of its cell body within the spinal cord in the lower region of your back all the way down your leg to your

toe. The axon frequently gives off side branches, or **collaterals**, along its course. The first portion of the axon, in conjunction with the region of the cell body where the axon emerges from the soma, is called the **axon hillock**. The axon hillock is the part of the neuron that has the greatest density of voltage-dependent Na^+ channels, making it the most easily excitable portion of the neuron and the *trigger zone* of the axon (it also has the most hyperpolarized action potential threshold). The axon hillock is the zone where action potentials can be triggered by a graded potential of sufficient magnitude. The action potentials are then conducted along the axon from the axon hillock to the typically

highly branched nerve cell ending at the **axon terminals**. These terminals release chemical messengers that simultaneously influence numerous other cells with which they come into close association. Functionally, therefore, the axon is the *conducting zone* (electrical wire) of the neuron, and the axon terminals constitute its *output zone* (electrical station). (The major exception to this typical neuronal structure and functional organization is found in neurons specialized to carry sensory information, a topic described in Chapter 4.)

Action potentials can be initiated only in portions of the membrane that have an abundance of voltage-gated Na^+ channels that can be triggered to open by a depolarizing event. Typically, regions of excitable cells where graded potentials take place do not undergo action potentials, because voltage-gated Na^+ channels are sparse there. Therefore, sites specialized for graded potentials do not undergo action potentials, even though they might be considerably depolarized. However, graded potentials can, before dying out, trigger action potentials in adjacent portions of the membrane by bringing these more sensitive regions to threshold through a local current flow spreading from the site of the graded potential. In a typical neuron, for example, graded potentials are generated in the dendrites and cell body in response to incoming chemical signals. If these graded potentials have sufficient magnitude by the time they have spread to the axon hillock, they initiate an action potential at this triggering zone.

Conduction via a nerve fibre

Once an action potential is initiated at the axon hillock, no further triggering event is necessary to activate the remainder of the nerve fibre. The impulse is automatically conducted throughout the neuron without further stimulation; this is accomplished by one of two methods of propagation: *contiguous conduction* or *saltatory conduction*.

Contiguous conduction involves the spread of the action potential along every patch of membrane down the length of the axon (*contiguous* means “touching” or “next to in sequence”). This process is illustrated in ▶ Figure 2-39, which is a schematic representation of a longitudinal section of the axon hillock and the portion of the axon immediately beyond it. The membrane at the axon hillock is at the peak of an action potential. The inside of the cell is positive in this active area, because Na^+ has already rushed into the nerve cell at this point. The remainder of the axon, still at resting potential and negative inside, is considered inactive. For the action potential to spread from the active to the inactive areas, the inactive areas must somehow be depolarized to threshold before they can undergo an action potential. This depolarization is accomplished by local current flow between the area already undergoing an action potential and the adjacent inactive area, similar to the current flow responsible for the spread of graded potentials. Because opposite charges attract, current can flow locally between the active area and the neighbouring inactive area on both the inside and the outside of the membrane. This local current flow in effect neutralizes or eliminates some of the unbalanced charges in the inactive area; that is, it reduces the number of opposite charges separated across

the membrane, thus reducing the potential in this area. This depolarizing effect quickly brings the involved inactive area to threshold, at which time the voltage-gated Na^+ channels in this region of the membrane are all thrown open, leading to an action potential in this previously inactive area. Meanwhile, the original active area returns to resting potential as a result of K^+ efflux.

In turn, beyond the new active area is another inactive area, so the same thing happens again. This cycle repeats itself in a chain reaction until the action potential has spread to the end of the axon. *Once an action potential is initiated in one part of a nerve cell membrane, a self-perpetuating cycle is initiated so that the action potential is propagated along the rest of the fibre automatically.* In this way, the axon is like a firecracker fuse that needs to be lit at only one end. Once ignited, the fire spreads down the fuse; it is not necessary to hold a match to every separate section of the fuse.

Note that the original action potential does not travel along the membrane. Instead, it triggers an identical new action potential in the adjacent area of the membrane, and this process is repeated along the axon's length. An analogy is the “wave” at a stadium. Each section of spectators stands up (the rising phase of an action potential), then sits down (the falling phase) in sequence, one after another, as the wave moves around the stadium. The wave, not individual spectators, travels around the stadium. Similarly, new action potentials arise sequentially down the axon. Each new action potential in the conduction process is a fresh local event that depends on the induced permeability changes and electrochemical gradients, which are virtually identical down the length of the axon. Consequently, the last action potential at the end of the axon is identical to the original one, no matter how long the axon. This is how an action potential is spread along the axon in an undiminished fashion, and, in this way, action potentials can serve as long-distance signals without attenuation or distortion.

This nondecremental propagation of an action potential contrasts with the decremental spread of a graded potential, which dies out over a very short distance because it cannot regenerate itself. ■ Table 2-5 summarizes the differences between graded potentials and action potentials, some of which are yet to be discussed.

One-way propagation

What ensures the one-way (unidirectional) propagation of an action potential away from the initial site of activation? Note in ▶ Figure 2-40 that once the action potential has been regenerated at a new neighbouring site (now positive inside) and the original active area has returned to resting (once again negative inside), the close proximity of opposite charges between these two areas is conducive to local current flow in the backward direction, and also in the forward direction into as yet unexcited portions of the membrane. If such backward current flow were able to bring the just-inactivated area to threshold, another action potential would be initiated right there and spread both forward and backward. However, if action potentials could move in both directions, the situation would be chaotic, with numerous action potentials bouncing back and forth along the axon until the nerve cell

FIGURE 2-39 Contiguous conduction. Local current flow between the active area at the peak of an action potential and the adjacent inactive area still at resting potential reduces the potential in this contiguous inactive area to threshold, which triggers an action potential in the previously inactive area. The original active area returns to resting potential, and the new active area induces an action potential in the next adjacent inactive area by local current flow as the cycle repeats itself down the length of the axon.

eventually fatigued. Fortunately, neurons are saved from this fate of oscillating action potentials by the **refractory period**, during which a new action potential cannot be initiated by normal events in a region that has just undergone an action potential.

The refractory period has two components: the *absolute refractory period* and the *relative refractory period* (► Figure 2-41). These two periods occur as a result of the changing status of the voltage-gated Na^+ and K^+ channels during and after an action potential. During the time that a particular patch of axonal

membrane is undergoing an action potential, it cannot initiate another action potential, no matter how strongly a triggering event stimulates it. This time period when a recently activated patch of membrane is completely refractory (meaning “stubborn,” or unresponsive) to further stimulation is known as the **absolute refractory period**. Once the voltage-gated Na^+ channels have flipped to their open, or activated, state, they cannot be triggered to open again in response to another depolarizing triggering event, no matter how strong, until resting potential is

TABLE 2-5 Comparison of Graded Potentials and Action Potentials

Graded Potentials	Action Potentials
Graded potential change; magnitude varies with magnitude of triggering event	All-or-none membrane response; magnitude of triggering event coded in frequency rather than amplitude of action potentials
Duration varies with duration of triggering event	Constant duration
Decremental conduction; magnitude diminishes with distance from initial site	Propagated throughout membrane in undiminishing fashion
Passive spread to neighbouring inactive areas of membrane	Self-regeneration in neighbouring inactive areas of membrane
No refractory period	Refractory period
Can be summed	Summation impossible
Can be depolarization or hyperpolarization	Always depolarization and reversal of charges
Triggered by stimulus, by combination of neurotransmitter with receptor, or by spontaneous shifts in leak-pump cycle	Triggered by depolarization to threshold, usually through spread of graded potential
Occurs in specialized regions of membrane designed to respond to triggering event	Occurs in regions of membrane with abundance of voltage-gated Na ⁺ channels

restored and the channels are reset to their original positions. The channels are in their inactive state. Accordingly, the absolute refractory period lasts the entire time from the opening of the voltage-gated Na⁺ channels' activation gates at threshold, through closure of their inactivation gates at the peak of the action potential, until the return to resting potential when the channels' activation gates close and inactivation gates open once again—that is, until the channels are in their “closed-but-capable-of-opening” conformation. Only then can they respond to another depolarization with an explosive increase in P_{Na⁺} to

initiate another action potential. Because of this absolute refractory period, one action potential must be over before another can be initiated at the same site.

Following the absolute refractory period is a **relative refractory period**, during which a second action potential can be produced only by a triggering event considerably stronger

FIGURE 2-40 Value of the refractory period. Backward current flow is prevented by the refractory period. During an action potential and slightly beyond, an area cannot be restimulated by normal events to undergo another action potential. Thus, the refractory period ensures that an action potential can be propagated only in the forward direction along the axon.

FIGURE 2-41 Absolute and relative refractory periods. During the absolute refractory period, the portion of the membrane that has just undergone an action potential cannot be restimulated. This period corresponds to the time during which the Na⁺ gates are not in their resting conformation. During the relative refractory period, the membrane can be restimulated only by a stronger stimulus than is usually necessary. This period corresponds to the time during which the K⁺ gates that opened during the action potential have not yet closed.

than is usually necessary. The relative refractory period occurs after the action potential is completed because of a twofold effect: lingering inactivation of the voltage-gated Na^+ channels and slow closing of the voltage-gated K^+ channels that opened at the peak of the action potential. During this time, fewer-than-normal voltage-gated Na^+ channels are in a position to be jolted open by a depolarizing triggering event. Simultaneously, K^+ continues to leave through its slow-to-close channels during the after hyperpolarization. The less-than-normal Na^+ entry in response to another triggering event is opposed by a persistent hyperpolarizing outward leak of K^+ through its not-yet-closed channels. Therefore, a greater-than-normal depolarizing triggering event is needed to bring the membrane to threshold during the relative refractory period. If threshold is reached, action potentials stimulated during the relative refractory period may be of smaller amplitude, depending upon the number of voltage-gated Na^+ channels that have recovered from inactivation and are in the closed, ready-to-open conformation.

By the time the original site has recovered from its refractory period and is capable of being restimulated by normal current flow, the action potential has been rapidly propagated in the forward direction only and is so far away that it can no longer influence the original site. Thus, *the refractory period ensures the one-way propagation of the action potential down the axon away from the initial site of activation.*

The refractory period and the frequency of action potentials

The refractory period is also responsible for setting an upper limit on the frequency of action potentials—that is, it determines the maximum number of new action potentials that can be initiated and propagated along a fibre in a given period of time. The original site must recover from its refractory period before a new action potential can be triggered to follow the preceding action potential. The length of the refractory period varies for different types of neurons. The longer the refractory period, the greater the delay before a new action potential can be initiated and the lower the frequency with which a nerve cell can respond to repeated or ongoing stimulation.

All-or-none fashion

If any portion of the neuronal membrane is depolarized to threshold, an action potential is initiated and relayed along the membrane in undiminished fashion. Furthermore, once threshold has been reached, the resultant action potential generally goes to maximal height. The reason for this effect is that the changes in voltage during an action potential result from ion movements down concentration and electrical gradients, and these gradients are not affected by the strength of the depolarizing triggering event. A triggering event stronger than one necessary to bring the membrane to threshold does not produce a larger action potential. However, a triggering event that fails to depolarize the membrane to threshold does not trigger an action potential at all. Thus, *an excitable membrane*

either responds to a triggering event with an action potential that spreads nondecrementally throughout the membrane, or it does not respond with an action potential at all. This property is called the **all-or-none law**.

This all-or-none concept is analogous to firing a gun. Either the trigger is not pulled sufficiently to fire the bullet (threshold is not reached), or it is pulled hard enough to elicit the full firing response of the gun (threshold is reached). Squeezing the trigger harder does not produce a greater explosion. Just as it is not possible to fire a gun halfway, it is not possible to cause a halfway action potential.

Check Your Understanding 2.7

1. Use your knowledge of the three different states of voltage-gated channels to differentiate between absolute and relative refractory periods.
2. Explain the relationship between refractory period and the frequency of action potential firing.

The threshold phenomenon allows some discrimination between important and unimportant stimuli or other triggering events. Stimuli too weak to bring the membrane to threshold do not initiate action potentials and therefore do not clutter up the nervous system by transmitting insignificant signals.

The strength of a stimulus and the frequency of action potentials

How is it possible to differentiate between two stimuli of varying strengths when both stimuli bring the membrane to threshold and generate action potentials of the same magnitude? For example, how can one distinguish between touching a warm object or touching a very hot object if both trigger identical action potentials in a nerve fibre relaying information about skin temperature to the central nervous system? The answer lies in part on the *frequency* with which the action potentials are generated. A stronger stimulus does not produce a larger action potential, but it does trigger a greater *number* of action potentials per second. For an illustration, see ▶ Figure 9-36 (p. 421), in which changes in blood pressure are coded by corresponding changes in the frequency of action potentials generated in the nerve cells monitoring blood pressure.

In addition, a stronger stimulus in a region causes more neurons to reach threshold, increasing the total information sent to the central nervous system. For example, lightly touch this page with your finger and note the area of skin in contact with the page. Now, press down more firmly and note that a larger surface area of skin is in contact with the page. Therefore, more neurons are brought to threshold with this stronger touch stimulus.

Once initiated, the velocity, or speed, with which an action potential travels down the axon depends on two

factors: (1) whether the fibre is myelinated, and (2) the diameter of the fibre. Contiguous conduction occurs in unmyelinated fibres. In this case, as just described, each individual action potential initiates an identical new action potential in the next contiguous (bordering) segment of the axon membrane so that every portion of the membrane undergoes an action potential as this electrical signal is conducted from the beginning to the end of the axon. A faster method of propagation, *saltatory conduction*, takes place in myelinated fibres. We now examine how a myelinated fibre compares with an unmyelinated fibre, and then how saltatory conduction compares with contiguous conduction.

Myelination and the speed of conduction

Myelinated fibres, as the name implies, are covered with myelin at regular intervals along the length of the axon (► Figure 2-42a). **Myelin** is composed primarily of lipids (phospholipids are 80 percent lipid and 20 percent protein). Because the water-soluble ions responsible for carrying current across the membrane cannot permeate this thick lipid barrier, the myelin coating acts as an insulator, just like plastic around an electrical wire, to prevent current leakage across the myelinated portion of the membrane. Myelin is not actually a part of the nerve cell but consists of separate myelin-forming cells that wrap themselves around the axon in a jelly-roll fashion (► Figures 2-42b and 2-42c). These myelin-forming cells are **oligodendrocytes** in the brain and spinal cord of the central nervous system and **Schwann cells** in nerves of the peripheral nervous system that run between the central nervous system and body regions. Between the myelinated regions are areas called the **nodes of Ranvier**, where the axonal membrane is bare and exposed to the ECF. The unmyelinated nodes of Ranvier are located at about 1 mm intervals along the length of the axon, with each nodal bare space about 2 µm long. Only at these bare spaces can current flow across the membrane to produce action potentials. Voltage-gated Na^+ channels are concentrated at the nodes, whereas the myelin-covered regions are almost devoid of these special passageways. By contrast, an unmyelinated fibre has a high density of voltage-gated Na^+ channels throughout its entire length. Recall that action potentials can be generated only at portions of the membrane furnished with an abundance of these channels.

The distance between the nodes is short enough that local current can travel from an active node to an adjacent inactive node before dying off. When an action potential occurs at one node, local current flow between this node and the oppositely charged adjacent node reduces the adjacent node's potential to threshold so that it undergoes an action potential, and so on. Consequently, in a myelinated nerve, the impulse “jumps” from node to node, like an athlete performing plyometric exercises jumping from the floor (node) over a box (myelin) to the floor (node), over and over again. This process is called **saltatory conduction** (*saltere* means “to jump”). Saltatory conduction propagates action potentials more rapidly than contiguous

conduction does, because the action potential is regenerated only at the unmyelinated axonal nodes and not between. In myelinated fibres, local current generated at an active node travels a longer distance, depolarizing the next node instead of the next section. Myelinated fibres conduct impulses about 50 times faster than unmyelinated fibres of comparable size. Thus, the most urgent types of information are transmitted via myelinated fibres, and nerve pathways that carry less urgent information are unmyelinated.

In addition to permitting action potentials to travel faster, a second advantage of myelination is that it conserves energy. Because the ion fluxes associated with action potentials are confined to the nodal regions, the energy-consuming $\text{Na}^+ - \text{K}^+$ pump does not need to restore as many ions to their respective sides of the membrane following propagation of an action potential.

Fibre diameter and the velocity of action potentials

Besides the effect of myelination, fibre diameter influences the speed with which an axon can conduct action potentials. The magnitude of current flow (i.e., the amount of charge that moves) depends not only on the difference in potential between two adjacent electrically charged regions but also on the resistance or hindrance to electrical-charge movement between the two regions. When fibre diameter increases, the resistance to local current decreases. Thus, the larger the fibre diameter, the faster action potentials can be propagated. For example, the giant squid has one of the largest axons (>1 mm diameter) known, and one of the fastest velocities of nerve impulses in the animal kingdom.

Large myelinated fibres, such as those supplying skeletal muscles, can conduct action potentials at a speed of up to 120 m/sec (268 mi/h), compared with a conduction velocity of 0.7 m/sec (2 mi/h) in small unmyelinated fibres, such as those supplying the digestive tract. This difference in speed of propagation is related to the urgency of the information being conveyed. A signal to skeletal muscles to execute a particular movement (e.g., to prevent you from falling as you trip on something) must be transmitted more rapidly than a signal to modify a slow-acting digestive process. Without myelination, axon diameters within urgent nerve pathways would have to be very large and cumbersome to achieve the necessary conduction velocities. Indeed, this is the case in many invertebrates. In the course of vertebrate evolution, the need for very large nerve fibres has been overcome by the development of the myelin sheath, allowing economic, rapid, long-distance signalling.

The presence of myelinating cells can be either of tremendous benefit or of tremendous detriment when an axon is cut, depending on whether the damage occurs in a peripheral nerve or in the central nervous system (CNS). Next we discuss the regeneration of damaged nerve fibres, a matter of crucial importance in spinal cord injuries or other trauma affecting nerves.

Neural Stem Cells and Spinal Cord Repair

2

Stem Cells

In the embryo, stem cells can differentiate into all of the specialized embryonic tissues. In an adult, stem cells act as a repair system for the body, replenishing specialized cells. They also maintain the normal turnover of regenerative organs, such as skin. Pluripotent adult stem cells (cells capable of having more than one potential outcome) are rare but can be found in a number of tissues, including umbilical cord blood. Most adult stem cells have a restricted lineage and as such are multipotent (they can generate several cell types, but those types are limited in number). The multipotent stem cell is generally referred to by its tissue of origin: the mesenchymal stem cell, adipose-derived stem cell, etc. Human stem cell research uses primarily multipotent cells that have the ability to proliferate in an undifferentiated state, to self-restore, and to form all the cell types of a particular tissue, for example, nervous tissue.

The field of stem cell research was born from the findings of Dr. Ernest McCulloch, a cellular biologist, and Dr. James Till, a biophysicist, in the 1960s. Together they conducted research on bone marrow cell injections into irradiated mice. Today, stem cell research holds great potential for therapeutic use in the regeneration of damaged organs.

Neural Stem Cells

Neural stem cells come from the nervous system itself, and mature into central nervous system cells. The most productive source of nervous system cells (e.g., neurons, glia, astrocytes, and oligodendrocytes) is embryonic neural tissue. In the embryo, neuroepithelial cells of the neural tube generate a variety of lineage-restricted (multipotent) precursor cells that migrate and differentiate into neurons, astrocytes, and oligodendrocytes. Central nervous system (CNS) stem cells have now been discovered in humans, and these could potentially be used to promote neurogenesis following injury and disease. Research suggests that transplanted neural stem cells can alter their fate in response to the environment into which they are reintroduced. Neural stem cells also can be isolated from different areas and grown in culture for prolonged periods without losing their multipotentiality. When the cells are transplanted back into the CNS, they have the capacity to migrate, integrate, and respond to local cues for differentiation.

Spinal Cord Repair

The findings from neural stem cell research point to a promising future for this cell in helping those with spinal cord injuries. One of the best

2.13 | Regeneration of Nerve Fibres

Whether or not a severed axon regenerates depends on its location. Cut axons in the peripheral nervous system can regenerate, whereas those in the central nervous system cannot.

Schwann cells

In the case of a cut axon in a peripheral nerve, the portion of the axon farthest from the cell body degenerates, and the surrounding Schwann cells phagocytize the debris. The Schwann cells themselves remain and form a **regeneration tube** to guide the regenerating nerve fibre to its proper destination. The remaining portion of the axon connected to the cell body starts to grow and move forward within the Schwann cell column by amoeboid movement. The growing axon tip “sniffs” its way forward in the proper direction, guided by a chemical secreted into the regeneration tube by the Schwann cells. Successful fibre regeneration is responsible for the return of sensation and movement after a period of time following traumatic peripheral nerve injuries, although regeneration is not always successful.

Oligodendrocytes

Fibres in the CNS, which are myelinated by oligodendrocytes rather than Schwann cells, do not have this regenerative ability. Actually, the axons themselves have the ability to regenerate, but the oligodendrocytes surrounding them synthesize certain proteins that inhibit axonal growth. This is in sharp contrast to how nerve growth is promoted by the Schwann cells that myelinate peripheral axons. Nerve growth in the brain and spinal cord is controlled by a delicate balance between *proteins that enhance nerve growth and those that inhibit nerve growth*. During fetal development, nerve growth in the CNS is possible when the brain and spinal cord are being formed. Researchers speculate that the nerve-growth inhibitors, which are produced late in fetal development in the myelin sheaths surrounding central nerve fibres, may normally serve as “guardrails” to keep new nerve endings from straying outside their proper paths. In this way, the growth-inhibiting action of oligodendrocytes may serve to stabilize the enormously complex structure of the CNS.

Growth inhibition is a disadvantage, however, when central axons need to be mended, as when the spinal cord has been severed accidentally. Damaged central fibres show immediate signs of repairing themselves after an injury, but within several weeks they start to degenerate, and scar tissue forms at the site of injury,

sources of cells for this treatment is neuronal-restricted precursors, from the developing spinal cord. These cells can be expanded in vitro and have the potential to differentiate into numerous neuronal types, such as motor neurons. Injury to the spinal cord is associated with damage to a particular region; the severity of the injury will dictate the size of the area affected. Function may be lost in the affected region because nerve fibres carrying information up and down the cord beyond that point are blocked.

For example, spinal cord injury to the cervical or thoracic region may result in the loss of control of the legs and bladder, because of the damage to nerve fibres that previously reached parts of the body below the injury. Researchers hope to use neural stem cells and precursors to replace the damaged or lost nerve cells.

Bridging the damaged area to allow axonal regeneration across and beyond the damaged area requires replacing the myelin as well. Thus, stem cells that mature into neurons and oligodendrocytes (which make myelin) are needed for most cellular repair in the injured spinal cord. Myelin is the biological insulation for nerve fibres. It is critical to the maintenance of electrical conduction in the CNS. When myelin is stripped away through disease or injury, sensory and motor

deficiencies result, and paralysis is common. Animal research has demonstrated that when adult human neural stem cells are injected into mice with spinal cord injuries, the transplanted stem cells differentiate into new oligodendrocyte cells that restore myelin around the damaged axons. Moreover, transplanted cells can differentiate into new neurons that form synaptic connections with mouse neurons. Mice that received human neural stem cells within a few days of getting spinal cord injuries have shown improvements in mobility as compared with control mice. For an update on some of the most current research, visit www.icord.org, a Canadian-led initiative focused on spinal cord injury.

halting any recovery. Therefore, damaged neuronal fibres in the brain and spinal cord never regenerate. (For another example of nerve degeneration and the human body's inability to regenerate, see Concepts, Challenges, and Controversies; p. 72)

Regeneration of cut central axons

In the future, with the help of exciting new findings, it may be possible to induce significant regeneration of damaged fibres in the CNS. Here are some current lines of research:

- Scientists have been able to induce significant nerve regeneration in rats with severed spinal cords by *chemically blocking the nerve-growth inhibitors*, thereby allowing the nerve-growth enhancers to promote abundant sprouting of new nerve fibres at the site of injury. One of the nerve-growth inhibitors, dubbed *Nogo*, was recently identified. Now investigators are trying to encourage axon regrowth in experimental animals with spinal cord injuries by using an antibody to Nogo.
- Other researchers are experimentally *using peripheral nerve grafts* to bridge the defect at an injured spinal cord site. These grafts contain the nurturing Schwann cells, which release proteins that enhance nerve growth.
- Another promising avenue under study involves *transplanting olfactory ensheathing glia* into the damaged site. Olfactory neurons, the cells that carry information about odours to the

brain, are replaced on a regular basis, unlike most neurons. The growing axons of these newly generated neurons enter the brain to form functional connections with appropriate neurons in the brain. This capability is promoted by special olfactory ensheathing glia, which wrap around and myelinate the olfactory axons. Early experimental evidence suggests that transplants of these special myelin-forming cells might help induce axonal regeneration in the CNS.

- Another avenue of hope is the recent discovery of *neural stem cells* (pp. 10–11). These cells might someday be implanted into a damaged spinal cord and coaxed into multiplying and differentiating into mature, functional neurons that will replace those lost.
- Yet another new strategy under investigation is *enzymatically breaking down inhibitory components in the scar tissue* that naturally forms at the injured site and prevents sprouting nerve fibres from crossing this barrier.
- Still other investigators are exploring other promising avenues of spurring repair of central axonal pathways, with the goal of enabling victims of spinal cord injuries to walk again.

You have now seen how an action potential is propagated along the axon and learned about the factors that influence the speed of this propagation. But what happens when an action potential reaches the end of the axon? We now turn our attention to this topic.

2.14 | Synapses and Neuronal Integration

When the action potential reaches the axon terminals, they release a chemical messenger that alters the activity of the cells on which the neuron terminates. A neuron may terminate on one of the three structures: (1) a muscle, (2) a gland, or (3) another neuron. Therefore, depending on where a neuron terminates, it can cause a muscle cell to contract, a gland cell to secrete, another neuron to convey an electrical message along a nerve pathway, or some other function. When a neuron terminates on a muscle or a gland, the neuron is said to **innervate** the structure. The following section focuses on the junction between two neurons: the synapse. (Sometimes the term *synapse* is used to describe a junction between any two excitable cells, but we will reserve this term for the junction between two neurons.)

Synapses

Typically, a synapse involves a junction between an axon terminal of one neuron, known as the *presynaptic neuron*, and the dendrites or cell body of a second neuron, known as the *postsynaptic neuron*. (*Pre* means “before,” and *post* means “after”; the presynaptic neuron lies before the synapse, and the postsynaptic neuron lies after the synapse.) The dendrites and, to a lesser extent, the cell body of most neurons receive thousands of synaptic inputs, which are axon terminals from many other neurons. Some neurons within the central nervous system receive as many as 100 000 synaptic inputs (► Figure 2-43).

The anatomy of one of these thousands of synapses is shown in ► Figure 2-44a. The axon terminal of the **presynaptic neuron**, which conducts its action potentials *toward* the synapse, ends in a slight swelling, the **synaptic knob**. The synaptic knob

contains **synaptic vesicles**, which store a specific chemical messenger, a **neurotransmitter** that has been synthesized and packaged by the presynaptic neuron. The synaptic knob comes into close proximity to, but does not actually directly touch, the **postsynaptic neuron**, the neuron whose action potentials are propagated *away* from the synapse. The space between the presynaptic and postsynaptic neurons is called the **synaptic cleft**.

Current does not directly spread from the presynaptic to the postsynaptic neuron, because no channels are present in the presynaptic membrane for passage of charge-carrying Na^+ and K^+ . Therefore, action potentials cannot electrically pass between the neurons. Instead, an action potential in the presynaptic neuron alters the postsynaptic neuron’s potential by chemical means. Excitation in synapses moves in one direction only, from the presynaptic neuron to the postsynaptic neuron; the reason for this will become apparent as you read further.

Neurotransmitters and signals

Here are the events that occur at a synapse (illustrated in ► Figure 2-44):

1. When an action potential in a presynaptic neuron has been propagated along the axon to the axon terminal (step **1**), this local change in potential opens another kind of voltage-gated channel: the voltage-gated calcium (Ca^{2+}) channels in the synaptic knob. Voltage-gated Ca^{2+} channels are a class of transmembrane ion channels that are activated by changes in electrical potential. Ca^{2+} channels are critical in neurons, and are common in other cell types.
2. Because Ca^{2+} is much more highly concentrated in the ECF and its electrical gradient is inward, this ion flows into the synaptic knob through the opened channels (step **2**).

► **FIGURE 2-43 Synaptic inputs to a postsynaptic neuron.** (a) Schematic representation of synaptic inputs (presynaptic axon terminals) to the dendrites and cell body of a single postsynaptic neuron. (b) Electron micrograph showing multiple presynaptic axon terminals to a single postsynaptic cell body

► **FIGURE 2-44 Synaptic structure and function.** Schematic representation of the structure of a single synapse. The circled numbers designate the sequence of events that take place at a synapse.

3. Ca^{2+} induces the release of a neurotransmitter from some of the synaptic vesicles into the synaptic cleft (step 3). A delay (i.e., synaptic delay) of 1–2 milliseconds occurs between the arrival of the action potential and the neurotransmitter release. This results from the conversion of the electrical impulse to the chemical signal. The more complex the pathway is, the greater the synaptic delay and the longer the *total reaction time* (*response to the stimulus*). The neurotransmitter release is accomplished by exocytosis (p. 48), though the molecular mechanism is not completely understood. Also, it is believed that the old vesicles used during exocytosis become part of the presynaptic membrane, and new vesicles are made from adjacent membrane.

4. The released neurotransmitter diffuses across the cleft and binds with specific protein receptors on the **subsynaptic membrane**, which is the postsynaptic membrane directly below the synaptic knob (step 4). The protein receptor has recognition sites specific for that neurotransmitter.

5. This binding triggers the opening of specific ion channels in the subsynaptic membrane, changing the ion permeability of the postsynaptic neuron (step 5). The binding of the neurotransmitter to the receptor triggers a postsynaptic response specific for that receptor. These are chemically gated channels, in contrast to the voltage-gated channels responsible for the action potential and for Ca^{2+} influx into the synaptic knob.

Because the presynaptic terminal releases the neurotransmitter and the subsynaptic membrane of the postsynaptic neuron has specific receptor sites for the neurotransmitter, the synapse can operate only in the direction from presynaptic to postsynaptic neuron. Additionally, these responses can be either *excitatory* or *inhibitory*, depending on the properties of the receptor.

Synapse behaviour

Neurons vary in the type of neurotransmitters they release, but does each neuron release only one type of neurotransmitter? No, not exactly. Neuroactive peptides and other neuroactive molecules can be contained in the same neuron. Mature neurons commonly contain one small-molecule transmitter and one or more peptides, and when released together by a presynaptic neuron they work synergistically on the same target cells. It also seems that the same neuron can release more than one neurotransmitter, depending on location. For example, it is known that motor neurons release acetylcholine (ACh; on muscle and on neurons in the spine), but it is also believed that they release the neurotransmitter glutamate on neurons in the spine. This means the concept of a neuron releasing only one neurotransmitter, or communication molecule, is too simplistic. However, here we focus on neurotransmitter release and its effects, not on all the potential neuroactive substances released by neurons, which is beyond the scope of this text.

Once the neurotransmitter binds with its subsynaptic receptor sites, a change in ion permeability ensues. There are

two types of synapses, depending on the permeability changes induced in the postsynaptic neuron by the combination of a specific neurotransmitter with its receptor sites: *excitatory synapses* and *inhibitory synapses*.

EXCITATORY SYNAPSES

At an **excitatory synapse**, the response to the binding of a neurotransmitter to the receptor is the opening of nonspecific cation channels within the subsynaptic membrane that permit simultaneous passage of Na^+ and K^+ through them. What makes these channels different from the Na^+ and K^+ channels described earlier is that permeability to both these ions is increased at the same time. How much of each ion diffuses through an open cation channel depends on their electrochemical gradients. At resting potential, both the concentration and electrical gradients for Na^+ favour its movement into the postsynaptic neuron, whereas only the concentration gradient for K^+ favours its movement outward. Therefore, the permeability change induced at an excitatory synapse results in the movement of a few K^+ ions out of the postsynaptic neuron, while a relatively larger number of Na^+ ions simultaneously enter this neuron. The result is net movement of positive ions into the cell. This makes the inside of the membrane slightly less negative than at resting potential, thereby producing a *small depolarization* of the postsynaptic neuron. Excitation and inhibition depend on the properties of the receptor, not the neurotransmitter. Note too that receptors coupled to Na^+ or Ca^{2+} channels are excitatory and, when activated, produce a depolarization of the postsynaptic membrane.

Activation of one excitatory synapse can rarely depolarize the postsynaptic neuron sufficiently to bring it to threshold. Too few channels are involved at a single subsynaptic membrane to permit enough ion flow to reduce the potential to threshold. This small depolarization, however, does bring the membrane of the postsynaptic neuron closer to threshold, increasing the likelihood that threshold will be reached (but further excitatory input is needed) and an action potential will occur. That is, the membrane is now more excitable (easier to bring to threshold) than when at rest. Accordingly, this change in postsynaptic potential occurring at an excitatory synapse is called an **excitatory postsynaptic potential (EPSP)** (► Figure 2-45a).

INHIBITORY SYNAPSES

At an **inhibitory synapse**, the binding of a different released neurotransmitter with its receptor sites increases the permeability of the subsynaptic membrane to either K^+ or Cl^- . Receptors coupled to Cl^- or K^+ channels are therefore inhibitory and produce a *small hyperpolarization* of the postsynaptic neuron—having greater internal negativity. In the case of increased P_{K^+} , more positive charges leave the cell via K^+ efflux, which leaves more negative charges behind on the inside. To hyperpolarize the membrane in the case of increased P_{Cl^-} , more negative charges enter the cell in the form of Cl^- ions (because Cl^- is in higher concentration outside the cell) than are driven out by the opposing electrical gradient established by the resting

► **FIGURE 2-45 Postsynaptic potentials.** (a) Excitatory synapse. An excitatory postsynaptic potential (EPSP) brought about by activation of an excitatory presynaptic input brings the postsynaptic neuron closer to threshold potential. (b) Inhibitory synapse. An inhibitory postsynaptic potential (IPSP) brought about by activation of an inhibitory presynaptic input moves the postsynaptic neuron farther from threshold potential.

membrane potential (p. 57). In either case, this small hyperpolarization moves the membrane potential even farther away from threshold (► Figure 2-45b), reducing the likelihood that the postsynaptic neuron will reach threshold and undergo an action potential. That is, the membrane is now less excitable (harder to bring to threshold by excitatory input) than when it is at resting potential. The membrane is said to be inhibited under these circumstances, and the small hyperpolarization of the postsynaptic cell is called an **inhibitory postsynaptic potential (IPSP)** (see Why It Matters).

In cells where the equilibrium potential for Cl^- exactly equals the resting potential, an increased P_{Cl^-} does not result in a hyperpolarization because there is no driving force to produce Cl^- movement. Opening of Cl^- channels in these cells tends to hold the membrane at resting potential, and this reduces the likelihood that threshold will be reached.

Note that EPSPs and IPSPs are produced by the opening of chemically gated channels, unlike action potentials, which are produced by the opening of voltage-gated channels.

IT IS NOT UNCOMMON FOR excitatory and inhibitory neurons to synapse on the same neuron. The arrival of an excitatory signal (EPSP) triggers a wave of depolarization along the membrane of a postsynaptic neuron. Inhibitory signals (IPSP) have an opposite effect. IPSP signals cause a wave of hyperpolarization along the membrane of a postsynaptic cell. When they arrive at the same neuron, these opposing signals travel along the postsynaptic membrane until they reach the axon terminal, and are integrated. If enough EPSPs arrive at the axon terminal simultaneously, the membrane potential rises above threshold, and an action potential forms. Arrival of the IPSPs lowers the membrane potential. If enough IPSPs have formed, these

inhibitory signals stop the neuron from firing. During stressful times, excitatory neurons in the amygdala fire rapidly, sending excitatory signals to other areas of the brain. This type of firing leads to a feeling of panic or fear. The IPSP interneurons in the amygdala modulate these emotions by releasing GABA (g-aminobutyric acid). Its recognition by postsynaptic receptors (e.g., GABAA) inhibits excitatory signals that result in feelings of panic and fear; thus, the inhibitory neurotransmitter GABA has a calming effect on our emotions and prevents us from becoming overwhelmed in stressful situations. GABA's inhibitory role is key in maintaining normal firing rates in many physiological systems.

Receptor combinations

Many different chemicals serve as neurotransmitters (Table 2-6). Even though neurotransmitters vary from synapse to synapse, the same neurotransmitter is always released at a particular synapse. Furthermore, at a given synapse, the binding of a neurotransmitter with its appropriate subsynaptic receptors always leads to the same change in permeability and the resultant change in potential of the postsynaptic membrane. That is, the response to a given neurotransmitter–receptor combination is always constant and produces the same response. Some neurotransmitters (e.g., *glutamate*, the most common excitatory neurotransmitter in the brain) typically bring about EPSPs, whereas others (e.g., *gamma-aminobutyric acid*, or GABA, the brain's main inhibitory neurotransmitter) always cause IPSPs. Still other neurotransmitters (e.g., *norepinephrine*) are quite variable, producing EPSPs at one synapse and IPSPs at a different synapse. This means that changes in permeability in the postsynaptic neuron differ in response to the binding of the same neurotransmitter to the subsynaptic receptor sites of different postsynaptic neurons.

Most of the time, each axon terminal releases only one neurotransmitter. Recent evidence suggests, however, that in some cases two different neurotransmitters can be released simultaneously from a single axon terminal. For example, *glycine* and GABA, both of which produce inhibitory responses, can be packaged and released from the same synaptic vesicles. Scientists speculate that the fast-acting glycine and more slowly acting GABA may complement each other in the control of activities that depend on precise timing: for example, coordination of complex movements.

Neurotransmitter removal

The alteration in membrane permeability responsible for the EPSP or IPSP continues as long as the neurotransmitter remains bound to the receptor sites. However, after it has produced the appropriate response in the postsynaptic neuron, the neurotransmitter must be inactivated or removed. This, so to say, wipes cleans the postsynaptic neuron, leaving it ready to receive

additional messages from the same or other presynaptic inputs. Several mechanisms can remove the neurotransmitter: it may (1) diffuse away from the synaptic cleft, (2) be inactivated by specific enzymes within the subsynaptic membrane, or (3) be actively taken back up into the axon terminal by transport mechanisms in the presynaptic membrane. Once the neurotransmitter is taken back up, it can be stored and later released again (recycled) in response to a subsequent action potential, or it may be destroyed by enzymes within the synaptic knob. What actually occurs depends on the particular synapse.

Grand postsynaptic potential

EPSPs and IPSPs are graded potentials. Unlike action potentials, which behave according to the all-or-none law, graded potentials can be of varying magnitude, have no refractory period, and can be summed (added on top of one another). What are the mechanisms and significance of summation?

The events that occur at a single synapse result in either an EPSP or an IPSP at the postsynaptic neuron. But if a single EPSP is inadequate to bring the postsynaptic neuron to threshold and an IPSP moves it even farther from threshold, how can an action potential be initiated in the postsynaptic neuron? The answer

TABLE 2-6 Some Common Neurotransmitters

Acetylcholine	Histamine
Dopamine	Glycine
Norepinephrine	Glutamate
Epinephrine	Aspartate
Serotonin	Gamma-aminobutyric acid (GABA)

lies in the thousands of presynaptic inputs (sum total) that a typical neuronal cell body receives from many other neurons. Some of these presynaptic inputs may be carrying sensory information from the environment; some may be signalling internal changes in homeostatic balance; others may be transmitting signals from control centres in the brain; and still others may arrive carrying other bits of information. At a given time, any number of these presynaptic neurons (probably hundreds) may be firing and thus influencing the postsynaptic neuron's level of activity. The total potential in the postsynaptic neuron, the **grand postsynaptic potential (GPSP)**, is a sum total of all EPSPs and IPSPs occurring at approximately the same time.

The postsynaptic neuron can be brought to threshold in two ways: (1) *temporal summation* and (2) *spatial summation*. To illustrate these methods of summation, we examine the possible interactions of three presynaptic inputs—two excitatory inputs (Ex1 and Ex2) and one inhibitory input (In1)—on a hypothetical postsynaptic neuron (▶ Figure 2-46). The recording shown in the figure represents the potential in a single postsynaptic cell; typically there are thousands of synapses.

TEMPORAL SUMMATION

Suppose that Ex1 has an action potential that causes an EPSP in the postsynaptic neuron. If later, after this EPSP has died off, another action potential occurs in Ex1, an EPSP of the same magnitude takes place (panel (a) in ▶ Figure 2-46). Next, suppose that

Ex1 has two action potentials in close succession (panel (b)). The first action potential in Ex1 produces an EPSP in the postsynaptic membrane. While the postsynaptic membrane is still partially depolarized from this first EPSP, the second action potential in Ex1 produces a second EPSP. The second EPSP adds on to the first EPSP, bringing the membrane to threshold, so an action potential occurs in the postsynaptic neuron. Graded potentials do not have a refractory period, so this additive effect is possible.

The summing of several EPSPs occurring very close together in time because of successive firing of a single presynaptic neuron is known as **temporal summation** (*tempus* means “time”). In reality, the situation is much more complex than just described. The sum of up to 50 EPSPs might be needed to bring the postsynaptic membrane to threshold. Each action potential in a single presynaptic neuron triggers the emptying of a certain number of synaptic vesicles. The amount of neurotransmitter released and the resultant magnitude of the change in postsynaptic potential are thus directly related to the frequency of presynaptic action potentials. One way, then, in which the postsynaptic membrane can be brought to threshold is through rapid, repetitive excitation from a single persistent input.

SPATIAL SUMMATION

Now consider the situation when both of the excitatory inputs are stimulated simultaneously in the postsynaptic neuron (panel (c) in ▶ Figure 2-46). An action potential in either Ex1 or Ex2

(a) If an excitatory presynaptic input (Ex1) is stimulated a second time after the first EPSP in the postsynaptic cell has died off, a second EPSP of the same magnitude will occur.

(b) If, however, Ex1 is stimulated a second time before the first EPSP has died off, the second EPSP will add onto, or sum with, the first EPSP, resulting in *temporal summation*, which may bring the postsynaptic cell to threshold.

(c) The postsynaptic cell may also be brought to threshold by *spatial summation* of EPSPs that are initiated by simultaneous activation of two (Ex1 and Ex2) or more excitatory presynaptic inputs.

(d) Simultaneous activation of an excitatory (Ex1) and inhibitory (In1) presynaptic input does not change the postsynaptic potential, because the resultant EPSP and IPSP cancel each other out.

▶ **FIGURE 2-46** Determination of the grand postsynaptic potential by the sum of activity in the presynaptic inputs. Two excitatory (Ex1 and Ex2) and one inhibitory (In1) presynaptic inputs terminate on this hypothetical postsynaptic neuron. The potential of the postsynaptic neuron is being recorded.

will produce an EPSP in the postsynaptic neuron; however, neither of these alone brings the membrane to threshold to elicit a postsynaptic action potential. But simultaneous action potentials in Ex1 and Ex2 produce EPSPs that add to each other, bringing the postsynaptic membrane to threshold, and making it possible for an action potential to occur. The summation of EPSPs originating simultaneously from several different presynaptic inputs (i.e., from different places, or points in space) is known as **spatial summation**. A second way, therefore, to elicit an action potential in a postsynaptic cell is through concurrent activation of several excitatory inputs. Again, in reality up to 50 simultaneous EPSPs are required to bring the postsynaptic membrane to threshold.

Similarly, IPSPs can undergo temporal and spatial summation. As IPSPs add together, however, they progressively move the potential farther from threshold.

CANCELLATION OF CONCURRENT EPSPS AND IPSPS

If an excitatory and an inhibitory input are simultaneously activated, the concurrent EPSP and IPSP more or less cancel each other out. The extent of cancellation depends on their respective magnitudes. In most cases, the postsynaptic membrane potential remains close to resting potential (panel (d) in ▶ Figure 2-46).

IMPORTANCE OF POSTSYNAPTIC NEURONAL INTEGRATION

The magnitude of the GPSP depends on the sum of activity in all the presynaptic inputs and, in turn, determines whether or not the neuron will undergo an action potential to pass information on to the cells on which the neuron terminates. The following oversimplified real-life example demonstrates the benefits of this neuronal integration. The explanation is not completely accurate technically, although the principles of summation are.

Assume for simplicity's sake that urination is controlled by a postsynaptic neuron that innervates the urinary bladder. When this neuron fires, the bladder contracts. (Actually, voluntary control of urination is accomplished by postsynaptic integration at the neuron controlling the external urethral sphincter, rather than the bladder itself.) As the bladder starts to fill with urine and becomes stretched, a reflex is initiated that ultimately produces EPSPs in the postsynaptic neuron responsible for causing bladder contraction. Partial filling of the bladder does not cause enough excitation to bring the neuron to threshold, so urination does not take place (panel (a) of ▶ Figure 2-46). As the bladder becomes progressively filled, the frequency of action potentials progressively increases in the presynaptic neuron that signals the postsynaptic neuron of the extent of bladder filling (Ex1 in panel (b)). When the frequency becomes great enough that the EPSPs are temporally summed to threshold, the postsynaptic neuron undergoes an action potential that stimulates bladder contraction.

What if the time is inopportune for urination to take place? IPSPs can be produced at the bladder postsynaptic neuron by presynaptic inputs originating in higher levels of the brain responsible for voluntary control (In1 in panel (d)). These voluntary IPSPs in effect cancel out the reflex EPSPs triggered by stretching of the bladder. Because the postsynaptic neuron

remains at resting potential and does not have an action potential, the bladder is prevented from contracting and emptying even though it is full.

What happens when a person's bladder is only partially filled—so that the presynaptic input originating from this source is insufficient to bring the postsynaptic neuron to threshold to cause bladder contraction—but a urine specimen has to be provided for laboratory analysis? The person can voluntarily activate an excitatory presynaptic neuron (Ex2 in panel (c)). The EPSPs originating from this neuron and the EPSPs of the reflex-activated presynaptic neuron (Ex1) are spatially summed to bring the postsynaptic neuron to threshold. This achieves the action potential necessary to stimulate bladder contraction, even though the bladder is not full.

This example illustrates the importance of postsynaptic neuronal integration. Each postsynaptic neuron in a sense “computes” all the input it receives and makes a “decision” about whether to pass the information on (i.e., whether threshold is reached and an action potential is transmitted down the axon). In this way, neurons serve as complex computational devices, or integrators. The dendrites function as the primary processors of incoming information. They receive and tally the signals coming in from all the presynaptic neurons, providing a sum total. Each neuron's output in the form of frequency of action potentials to other cells (muscle cells, gland cells, or other neurons) reflects the balance of activity in the inputs it receives via EPSPs or IPSPs from the thousands of other neurons that terminate on it. Each postsynaptic neuron filters out and does not pass on information it receives that is not significant enough to bring it to threshold. If every action potential in every presynaptic neuron that impinges on a particular postsynaptic neuron were to cause an action potential in the postsynaptic neuron, the neuronal pathways would be overwhelmed with trivia. Only if an excitatory presynaptic signal is reinforced by other supporting signals through summation will the information be passed on. Furthermore, interaction of postsynaptic potentials provides a way for one set of signals to offset another set (IPSPs negating EPSPs). This allows a fine degree of discrimination and control in determining what information will be passed on.

Next we examine why action potentials are initiated at the axon hillock.

Check Your Understanding 2.8

1. Compare and contrast excitatory synapses and inhibitory synapses.
2. Explain what is meant by temporal and spatial summation and why they are important.

Action potentials at the axon hillock

Threshold potential is not uniform throughout the postsynaptic neuron. The lowest threshold is present at the axon hillock, because this region has a much greater density of voltage-gated Na^+ channels than anywhere else in the neuron. The greater

density of these voltage-sensitive channels makes the axon hillock considerably more responsive than the dendrites or the remainder of the cell body to changes in potential. The latter regions have a significantly higher threshold than the axon hillock. Because of local current flow, changes in membrane potential (EPSPs or IPSPs) occurring anywhere on the dendrites or cell body spread throughout the dendrites, cell body, and axon hillock. When summation of EPSPs takes place, the lower threshold of the axon hillock is reached first, whereas the dendrites and cell body at the same potential are still considerably below their own, much higher thresholds. Therefore, an action potential originates in the axon hillock and is propagated from there to the end of the axon.

Neuropeptides as neuromodulators

In addition to the classical neurotransmitters just described, some neurons also release *neuropeptides*. Neuropeptides differ from classical neurotransmitters in several important ways (Table 2-7). **Classical neurotransmitters** are small, rapid-acting molecules that typically trigger the opening of specific ion channels to bring about a change in potential in the postsynaptic neuron (an EPSP or IPSP) within a few milliseconds or less. Most classical neurotransmitters are synthesized and packaged locally in synaptic vesicles in the cytosol of the axon terminal. These chemical messengers are primarily amino acids or closely related compounds.

Neuropeptides are larger molecules made up of anywhere from 2 to about 40 amino acids. They are synthesized in the neuronal cell body in the endoplasmic reticulum and Golgi complex and are subsequently moved by axonal transport along the microtubular highways to the axon terminal. Neuropeptides

are not stored within the small synaptic vesicles with the classical neurotransmitter, but instead are packaged in large **dense-core vesicles**, which are also present in the axon terminal. The dense-core vesicles undergo Ca^{2+} -induced exocytosis and release neuropeptides at the same time as the neurotransmitter is released from the synaptic vesicles. An axon terminal typically releases only a single classical neurotransmitter, but the same terminal may also contain one or more neuropeptides that are cosecreted along with the neurotransmitter.

Even though neuropeptides are currently the subject of intense investigation, our knowledge about their functions and control is still limited. They are known to diffuse locally and act on other adjacent neurons at much lower concentrations than do classical neurotransmitters, and they bring about slower, more prolonged responses. Some neuropeptides released at synapses may function as true neurotransmitters, but most are believed to function as neuromodulators. **Neuromodulators** are chemical messengers that do not cause the formation of EPSPs or IPSPs, but rather bring about long-term changes that subtly *modulate*—depress or enhance—the action of the synapse. They bind to neuronal receptors at nonsynaptic sites (i.e., not at the subsynaptic membrane), and they do not directly alter membrane permeability and potential. Neuromodulators may act at either presynaptic or postsynaptic sites. For example, a neuromodulator may influence the level of an enzyme involved in the synthesis of a neurotransmitter by a presynaptic neuron, or it may alter the sensitivity of the postsynaptic neuron to a particular neurotransmitter by causing long-term changes in the number of subsynaptic receptor sites for the neurotransmitter. In this way, neuromodulators delicately fine-tune the synaptic response. The effect may last for days or even months or years. Whereas neurotransmitters are involved in rapid communication between

■ **TABLE 2-7** Comparison of Classical Neurotransmitters and Neuropeptides

Characteristic	Classical Neurotransmitters	Neuropeptides
Size	Small; one amino acid or similar chemical	Large; 2 to 40 amino acids in length
Site of Synthesis	Cytosol of synaptic knob	Endoplasmic reticulum and Golgi complex in cell body; travel to synaptic knob by axonal transport
Site of Storage	In small synaptic vesicles in axon terminal	In large dense-core vesicles in axon terminal
Site of Release	Axon terminal	Axon terminal; may be cosecreted with neurotransmitter
Speed and Duration of Action	Rapid, brief response	Slow, prolonged response
Site of Action	Subsynaptic membrane of postsynaptic cell	Nonsynaptic sites on either presynaptic or postsynaptic cell at much lower concentrations than classical neurotransmitters
Effect	Usually alter potential of postsynaptic cell by opening specific ion channels	Usually enhance or suppress synaptic effectiveness by long-term changes in neurotransmitter synthesis or postsynaptic receptor sites (act as neuromodulators)

neurons, neuromodulators are involved with more long-lasting events, such as learning and motivation.

Interestingly, the synaptically released neuromodulators include many substances that also have distinctive roles as hormones, which are released into the blood from endocrine tissues. For example, *cholecystokinin* (CCK), a well-known hormone released from the small intestine, is involved in digestive activities such as causing the gallbladder to contract and release bile into the intestine (see Chapter 15). However, CCK has also been found in axon terminal vesicles in the brain, where it is believed to cause the feeling of satiation. In many instances, neuropeptides are named for their first-discovered role as hormones, as is the case with cholecystokinin (*chole* means “bile”; *cysto* means “bladder”; *kinin* means “contraction”). It appears that a number of chemical messengers are quite versatile and can assume different roles, depending on their source, their distribution, and their interaction with different cell types.

Presynaptic inhibition or facilitation

Besides neuromodulation, presynaptic inhibition or facilitation is another means of depressing or enhancing synaptic effectiveness. Sometimes a third neuron can influence activity between a presynaptic ending and a postsynaptic neuron. A presynaptic axon terminal (labelled A in ▶ Figure 2-47) may itself be innervated by another axon terminal (labelled B). The neurotransmitter released from modulatory terminal B binds with receptor sites on terminal A. This binding alters the amount of neurotransmitter released from terminal A in response to action potentials. If the amount of neurotransmitter released from A is reduced, the phenomenon is known as **presynaptic inhibition**. If the release of neurotransmitter is enhanced, the effect is called **presynaptic facilitation**.

Here, we look more closely at how this process works. Recall that Ca^{2+} entry into an axon terminal causes the release of

neurotransmitter by exocytosis of synaptic vesicles. The amount of neurotransmitter released from terminal A depends on how much Ca^{2+} enters this terminal in response to an action potential. Ca^{2+} entry into terminal A, in turn, can be influenced by activity in modulatory terminal B. Consider the example of presynaptic inhibition represented in ▶ Figure 2-47. The amount of neurotransmitter released from presynaptic terminal A, an excitatory input in this example, influences the potential in the postsynaptic neuron (C) at which it terminates. Firing of A, alone, brings about an EPSP in postsynaptic neuron C. Now consider that B is stimulated simultaneously with A. When neurotransmitter from terminal B binds to terminal A, Ca^{2+} entry into terminal A is reduced. Less Ca^{2+} entry means less neurotransmitter release from A. Note that modulatory neuron B can suppress neurotransmitter release from A only when A is firing. If this presynaptic inhibition by B prevents A from releasing its neurotransmitter, the formation of EPSPs on postsynaptic membrane C from input A is specifically prevented. As a result, no change in the potential of the postsynaptic neuron occurs despite action potentials in A.

Could the same inhibitory action result from the simultaneous production of an IPSP through the activation of an inhibitory input that negates an EPSP produced by the activation of A? Not quite. Activation of an inhibitory input to cell C would produce an IPSP in cell C, but this IPSP could cancel out not only an EPSP from excitatory input A but also any EPSPs produced by other excitatory terminals, such as terminal D. The entire postsynaptic membrane is hyperpolarized by IPSPs, thereby negating (cancelling) excitatory information fed into any part of the cell from any presynaptic input. By contrast, presynaptic inhibition (or presynaptic facilitation) works in a much more specific way than does the action of inhibitory inputs to the postsynaptic cell. Presynaptic inhibition provides a means by which certain inputs to the postsynaptic neuron can be *selectively* inhibited without affecting the contributions of any other inputs. For example,

▶ **FIGURE 2-47 Presynaptic inhibition.** A, an excitatory terminal ending on postsynaptic cell C, is itself innervated by inhibitory terminal B. Stimulation of terminal A alone produces an EPSP in cell C, but simultaneous stimulation of terminal B prevents the release of excitatory neurotransmitter from terminal A. Consequently, no EPSP is produced in cell C despite the fact that terminal A has been stimulated. Such presynaptic inhibition selectively depresses activity from terminal A without suppressing any other excitatory input to cell C. Stimulation of excitatory terminal D produces an EPSP in cell C, even though inhibitory terminal B is simultaneously stimulated, because terminal B only inhibits terminal A.

the firing of B specifically prevents the formation of an EPSP in the postsynaptic neuron from excitatory presynaptic neuron A, but does not have any influence on other excitatory presynaptic inputs. Excitatory input D can still produce an EPSP in the postsynaptic neuron even when B is firing. This type of neuronal integration is another means by which electrical signalling between nerve cells can be carefully fine-tuned.

Drugs, diseases, and transmission

A drug is any biological substance that when consumed will in some way alter the biological function of the organism. The vast majority of drugs that influence the nervous system perform their function by altering synaptic mechanisms. Synaptic drugs may block an undesirable effect or enhance a desirable effect. Possible drug actions include (1) altering the synthesis, axonal transport, storage, or release of a neurotransmitter; (2) modifying neurotransmitter interaction with the postsynaptic receptor; (3) influencing neurotransmitter reuptake or destruction; and (4) replacing a deficient neurotransmitter with a substitute transmitter.

For example, cocaine blocks the reuptake of the neurotransmitter *dopamine* at presynaptic terminals. It does so by binding competitively with the dopamine reuptake transporter, which is a protein molecule that picks up released dopamine from the synaptic cleft and shuttles it back to the axon terminal. With cocaine occupying the dopamine transporter, dopamine remains in the synaptic cleft longer than usual and continues to interact with its postsynaptic receptor sites. The result is prolonged activation of neural pathways that use this chemical as a neurotransmitter. Among these pathways are those that play a role in emotional responses, especially feelings of pleasure. Thus, cocaine locks the switch in the neural pleasure pathway in the “on” position.

Cocaine is addictive because it causes the neurons involved to generate long-term molecular adaptations, such that they cannot transmit normally across synapses without increasingly higher doses of the drug. The postsynaptic cells become accustomed to high levels of stimulation; they become “hooked” on the drug. The term **tolerance** refers to this *desensitization* to an addictive drug so that the user needs greater quantities of the drug to achieve the same effect. Specifically, with prolonged use of cocaine, the number of dopamine receptors in the brain is reduced in response to the glut of the abused substance. As a result of this desensitization, the user must steadily increase the dosage of the drug to get the same “high,” or sensation of pleasure. When the cocaine molecules diffuse away, the sense of pleasure evaporates, because the normal level of dopamine activity does not sufficiently “satisfy” the overly needy demands of the postsynaptic cells for stimulation. Cocaine users reaching this low become frantic and profoundly depressed. Only more cocaine makes them feel good again. But repeated use of cocaine modifies responsiveness to the drug. Over the course of abuse, the user often no longer can derive pleasure from the drug but suffers unpleasant *withdrawal symptoms* once the effect of the drug has worn off. Furthermore, the amount of cocaine needed to overcome the devastating crashes progressively increases.

The user typically becomes **addicted** to the drug, compulsively seeking out and taking the drug at all costs, first to experience the pleasurable sensations and later to avoid the negative withdrawal symptoms, even when the drug no longer provides pleasure. Cocaine is abused by millions who have become addicted to its mind-altering properties, with devastating social and economic effects.

Whereas cocaine abuse leads to excessive dopamine activity, **Parkinson’s disease (PD)** is attributable to a deficiency of dopamine in the *basal nuclei*, a region of the brain involved in controlling complex movements. This movement disorder is characterized by muscular rigidity and involuntary tremors at rest, such as involuntary rhythmic shaking of the hands or head. The standard treatment for PD is the administration of *levodopa (L-dopa)*, a precursor of dopamine. Dopamine itself cannot be administered because it is unable to cross the blood-brain barrier (discussed in Chapter 3), but L-dopa can enter the brain from the blood. Once inside the brain, L-dopa is converted into dopamine, thus substituting for the deficient neurotransmitter. This therapy greatly alleviates the symptoms associated with the deficit in most patients. This condition is described further in the discussion of the basal nuclei (Chapter 3, Section 3.9).

Synaptic transmission is also vulnerable to neural toxins, which may cause nervous system disorders by acting at either presynaptic or postsynaptic sites. For example, two different neural poisons, tetanus toxin and strychnine, act at different synaptic sites to block inhibitory impulses while leaving excitatory inputs unchecked. Tetanus toxin prevents the release of an inhibitory neurotransmitter, GABA, and therefore blocks the inhibitory presynaptic inputs to neurons that supply the skeletal muscles. Unchecked excitatory inputs to these neurons result in uncontrolled muscle spasms. These spasms occur especially in the jaw muscles early in the disease, giving rise to the common name of *lockjaw* for this condition. Later they progress to the muscles responsible for breathing, at which point death occurs.

Strychnine, in contrast, competes with another inhibitory neurotransmitter, glycine, at the postsynaptic receptor site. This poison combines with the receptor but does not directly alter the potential of the postsynaptic cell in any way. Instead, strychnine blocks the receptor so that it is not available for interaction with glycine when the latter is released from the inhibitory presynaptic ending. As a result, postsynaptic inhibition (formation of IPSPs) is abolished in nerve pathways that use glycine as an inhibitory neurotransmitter. Unchecked excitatory pathways lead to convulsions, muscle spasticity, and death.

Tetanus toxin and strychnine poisoning have similar outcomes. However, one poison (tetanus toxin) prevents the presynaptic release of a specific inhibitory neurotransmitter, and the other (strychnine) blocks specific postsynaptic inhibitory receptors. Other drugs and diseases that influence synaptic transmission are too numerous to mention, but as these examples illustrate, any site along the synaptic pathway is vulnerable to interference, either pharmacologic (drug induced) or pathologic (disease induced).

Neurons: complex converging and diverging pathways

Two important relationships exist between neurons: convergence and divergence. A given neuron may have many other neurons synapsing on it. Such a relationship is known as **convergence** (► Figure 2-48). Through this converging input, a single cell is influenced by thousands of other cells. This single cell, in turn, influences the level of activity in many other cells by divergence of output. The term **divergence** refers to the branching of axon terminals so that a single cell synapses with and influences many other cells.

Note that a particular neuron is postsynaptic to the neurons converging on it but presynaptic to the other cells at which it terminates. So the terms *presynaptic* and *postsynaptic* refer only to a single synapse. Most neurons are presynaptic to one group of neurons and postsynaptic to another group.

There are an estimated 100 billion neurons and 10^{14} (100 quadrillion) synapses in the brain alone! When you consider the vast and intricate interconnections possible between these neurons through converging and diverging pathways, you can begin to imagine how complex the wiring mechanism of our nervous system really is. Even the most sophisticated computers are far less complex than the human brain. The “language” of the nervous system—that is, all communication between neurons—is in the form of graded potentials, action potentials, neurotransmitter signalling across synapses, and other nonsynaptic forms of chemical chatter. All activities for which the nervous system is responsible—every sensation you feel, every command to move a muscle, every thought, every emotion, every memory, every spark of creativity—depend on the patterns of electrical and chemical signalling between neurons along these complexly wired neural pathways.

Chapter in Perspective: Focus on Homeostasis

The ability of cells to perform functions essential for their own survival as well as specialized tasks that help maintain homeostasis within the body ultimately depends on the successful, cooperative operation of the plasma membrane and the intracellular components. For example, to support life-sustaining activities, all cells must generate energy, in a usable form, from nutrient molecules. Energy is generated intracellularly by chemical reactions that take place within the cytosol and mitochondria. Additionally, many cellular functions require the movement of molecules either into or out of the cell, which can only be accomplished by the many different plasma membrane transport systems.

In addition to being essential for basic cell survival, many of the specialized tasks performed by cells that contribute to homeostasis require the production of cellular energy and the regulation of the intracellular environment. Here are some examples:

- Nerve and endocrine cells both release protein chemical messengers that are important in regulatory activities aimed at maintaining homeostasis. These protein chemical messengers (neurotransmitters in nerve cells and hormones in endocrine

► FIGURE 2-48 Convergence and divergence

cells) are all produced by the endoplasmic reticulum and Golgi complex and released by exocytosis from the cell when needed.

- The ability of muscle cells to contract depends not only on their highly developed cytoskeletal microfilaments sliding past one another but also on the vast amounts of ATP produced within their mitochondria. Muscle contraction is responsible for many homeostatic activities, including (1) contracting the heart muscle, which pumps life-supporting blood throughout the body; (2) contracting the muscles attached to bones, which enables the body to procure food; and (3) contracting the muscle in the walls of the stomach and intestine, which moves the food along the digestive tract so that ingested nutrients can be progressively broken down into a form that can be absorbed into the blood for delivery to the cells.

As we begin to examine the various organs and systems, keep in mind that proper cell functioning is the foundation of all organ activities.

Objective Questions (Answers on p. A-37)

1. The barrier that separates and controls movement between the cell contents and the extracellular fluid is the _____.
2. The chemical that directs protein synthesis and serves as a genetic blueprint is _____, which is found in the _____ of the cell.
3. The cytoplasm consists of _____, which are specialized, membrane-enclosed intracellular compartments, and a gel-like mass known as _____, which contains an elaborate protein network called the _____.
4. The universal energy carrier of the body is _____.
5. The largest cells in the human body can be seen by the unaided eye. (*True or false?*)
6. The nonpolar tails of the phospholipid molecules bury themselves in the interior of the plasma membrane. (*True or false?*)
7. The hydrophobic regions of the molecules composing the plasma membrane correspond to the two dark layers of this structure visible under an electron microscope. (*True or false?*)
8. Using the following answer code, indicate which form of energy production is being described:

___ 1. takes place in the mitochondrial matrix	
___ 2. produces H ₂ O as a by-product	
___ 3. results in a rich yield of ATP	(a) glycolysis
___ 4. takes place in the cytosol	(b) citric acid cycle
___ 5. processes acetyl CoA	(c) electron transport chain
___ 6. located in the mitochondrial inner-membrane cristae	
___ 7. converts glucose into two pyruvic acid molecules	
___ 8. uses molecular oxygen	
9. Using the answer code on the right, indicate which membrane component is responsible for the function in question:

___ 1. channel formation	
___ 2. barrier to passage of water-soluble substances	
___ 3. receptor sites	(a) lipid bilayer
___ 4. membrane fluidity	(b) proteins
___ 5. recognition of "self"	(c) carbohydrates
___ 6. membrane-bound enzymes	
___ 7. structural boundary	
___ 8. carriers	
10. Using the answer code on the right, indicate the direction of net movement in each case:

___ 1. simple passive diffusion	(a) movement from high to low concentration
___ 2. facilitated diffusion	(b) movement from low to high concentration
___ 3. primary active transport	
___ 4. Na ⁺ during secondary active transport	
___ 5. cotransported molecule during secondary active transport	
___ 6. water with regard to the water concentration gradient during osmosis	
___ 7. water with regard to the solute concentration gradient during osmosis	
11. Using the answer code on the right, indicate the type of cell junction described:

___ 1. adhering junction	(a) gap junction
___ 2. impermeable junction	(b) tight junction
___ 3. communicating junction	(c) desmosome
___ 4. made up of connexons, which permit passage of ions and small molecules between cells	
___ 5. consists of interconnecting fibres, which spot-rivet adjacent cells	
___ 6. formed by an actual fusion of proteins on the outer surfaces of two interacting cells	
___ 7. important in tissues subject to mechanical stretching	
___ 8. important in synchronizing contractions within heart and smooth muscle by allowing spread of electrical activity between the cells composing the muscle mass	
___ 9. important in preventing passage between cells in epithelial sheets that separate compartments of two different chemical compositions	
12. Through its unequal pumping, the Na⁺ – K⁺ pump is directly responsible for separating sufficient charges to establish a resting membrane potential of –70 mV. (*True or false?*)
13. At resting membrane potential, there is a slight excess of negative charges on the inside of the membrane, with a corresponding slight excess of positive charges on the outside. (*True or False?*)
14. Following an action potential, there is more K⁺ outside the cell than inside because of the efflux of K⁺ during the falling phase. (*True or false?*)
15. Postsynaptic neurons can either excite or inhibit presynaptic neurons. (*True or false?*)
16. The one-way propagation of action potentials away from the original site of activation is ensured by the _____.
17. The _____ is the site of action potential initiation in most neurons because it has the lowest threshold.
18. A junction in which electrical activity in one neuron influences the electrical activity in another neuron by means of a neurotransmitter is called a _____.
19. Summing of EPSPs occurring very close together in time as a result of repetitive firing of a single presynaptic input is known as _____.

20. Using the answer code on the right, indicate which potential is being described:

- | | |
|---|----------------------|
| ___ 1. behaves in all-or-none fashion | (a) graded potential |
| ___ 2. magnitude of the potential change varies with the magnitude of the triggering response | (b) action potential |
| ___ 3. decremental spread away from the original site | |
| ___ 4. spreads throughout the membrane in undiminishing fashion | |
| ___ 5. serves as a long-distance signal | |
| ___ 6. serves as a short-distance signal | |

Written Questions

- Compare exocytosis and endocytosis.
- Define *secretion*, *pinocytosis*, *receptor-mediated endocytosis*, and *phagocytosis*.
- Describe the structure of mitochondria, and explain their role in oxidative phosphorylation.
- Describe the fluid mosaic model of membrane structure.
- What are the functions of the three major types of protein fibres in the extracellular matrix?
- What two properties of a particle influence whether it can permeate the plasma membrane?
- List and describe the methods of membrane transport. Indicate what types of substances are transported by each method, and state whether each is a passive or active means of transport.
- List and describe the types of intercellular communication.
- Define the term *signal transduction*.
- Distinguish between a first messenger and a second messenger.
- What are the two types of excitable tissue?
- Define the following terms: *polarization*, *depolarization*, *hyperpolarization*, *repolarization*, *resting membrane potential*, *threshold potential*, *action potential*, *refractory period*, and *all-or-none law*.
- Describe the permeability changes and ion fluxes that occur during an action potential.
- Compare the events that occur at excitatory and inhibitory synapses.
- Discuss the possible outcomes of the grand postsynaptic potential brought about by interactions between EPSPs and IPSPs.
- Discuss the possible outcomes of the grand postsynaptic potential brought about by interactions between EPSPs and IPSPs.

Quantitative Exercises (Solutions on p. A-35 and A-36)

(See Appendix D, Principles of Quantitative Reasoning)

- Each “turn” of the Krebs cycle
 - generates 3 NAD⁺, 1 FADH, and 2 CO₂
 - generates 1 GTP, 2CO₂, and 1 FADH₂
 - consumes 1 pyruvate and 1 oxaloacetate
 - consumes an amino acid
- Consider how much ATP you synthesize in a day. Assume that you consume 1 mol of O₂ per hour or 24 mol/day (a mole is the number of grams of a chemical equal to its molecular weight). About 6 mol of ATP are produced per mole of O₂ consumed. The molecular weight of ATP is 507. How many grams of ATP do you produce per day at this rate? Given that 1000 g equal 2.2 lbs., how many pounds of ATP do you produce per day at this rate? (This is under relatively inactive conditions!)
- Under resting circumstances a person produces about 144 mol of ATP per day (73 000 g ATP/day). The amount of *free energy* represented by this amount of ATP can be calculated as follows: cleavage of the terminal phosphate bond from ATP results in a decrease of free energy by approximately 7300 cal/mol. This is a crude measure of the energy available to do work that is contained in the terminal phosphate bond of the ATP molecule. How many calories, in the form of ATP, are produced per day by a resting individual, crudely speaking?
- Calculate the number of cells in the body of an average 68 kg (150 lb.) adult. (This will only be accurate to about 1 part in 10 but should give you an idea how this commonly quoted number is arrived at.) Assume all cells are spheres 20 µm in diameter. The volume of a sphere can be determined by the equation. (*Hint*: We know that about two-thirds of the water in the body is intracellular, and the density of cells is nearly 1 g/mL. The proportion of the mass made up of water is about 60 percent.)
- If sucrose is injected into the bloodstream, it tends to stay out of the cells (cells do not use sucrose directly). If it doesn't go into cells, where does it go? In other words, how much “space” is in the body that is not inside some cell? Sucrose can be used to determine this space. Suppose 150 mg of sucrose is injected into a 55 kg woman. If the concentration of sucrose in her blood is 0.015 mg/mL, what is the volume of her extracellular space, assuming that no metabolism is occurring and that the blood sucrose concentration is equal to the sucrose concentration throughout the extracellular space?
- When using the Nernst equation for an ion that has a valence other than 1, you must divide the potential by the valence. Thus, for Ca²⁺ the Nernst equation becomes

$$E = \frac{61\text{mV}}{z} \log \frac{C_o}{C_i}$$

Use this equation to calculate the Nernst (equilibrium) potentials from the following sets of data:

- Given $[\text{Ca}^{2+}]_o = 1 \text{ mM}$, $[\text{Ca}^{2+}]_i = 100 \text{ nM}$, find $E_{\text{Ca}^{2+}}$,
 - Given $[\text{Cl}^-]_o = 110 \text{ mM}$, $[\text{Cl}^-]_i = 10 \text{ mM}$, find E_{Cl^-} ,
7. One of the important uses of the Nernst equation is in describing the flow of ions across cell membranes. Ions move under the influence of two forces: the concentration gradient (given in electrical units by the Nernst equation), and the electrical gradient (given by the membrane voltage). This is summarized by *Ohm's law*, as follows:

$$I_x = G_x (V_m - E_x)$$

This equation describes the movement of ion x across the membrane. I is the current in amperes (A); G is the conductance, a measure of the permeability of x, in Siemens (S), which is $\Delta I / \Delta V$; V_m is the membrane voltage; and E_x is the equilibrium potential of ion x. Not only does this equation tell us how large the current is but it also tells us in what direction the current is flowing. By convention, a negative value of the current represents either a positive ion entering the cell or a negative ion leaving the cell. The opposite is true of a positive value of the current.

- Using the following information, calculate the magnitude of I_{Na^+}

$$[\text{Na}^+]_o = 145 \text{ mM}, [\text{Na}^+]_i = 15 \text{ mM}$$

$$G_{\text{Na}^+} = 1 \text{ nS}, V_m = -70 \text{ mV}$$

- Is Na^+ entering or leaving the cell?
 - Is Na^+ moving with or against the concentration gradient?
 - Is it moving with or against the electrical gradient?
8. Another important use of the Nernst equation is in determining the resting membrane potential of a cell. The cell resting membrane potential is a weighted average of the equilibrium potentials of all permeant ions. The weighting factor is the relative permeability (conductance) to that ion. For a cell permeable only to Na^+ and K^+ , this equation is

$$V_m = \{G_{\text{Na}^+} / G_T\} E_{\text{Na}^+} + \{G_{\text{K}^+} / G_T\} E_{\text{K}^+}$$

In this equation, G_T is the total conductance (in this case,

- Given the following information, calculate V_m :

$$G_{\text{Na}^+} = 1 \text{ nS}, G_{\text{K}^+} = 5.3 \text{ nS}, E_{\text{Na}^+} = 59.1 \text{ mV}$$

$$E_{\text{K}^+} = -9.44 \text{ mV}$$

- What would happen to V_m if $[\text{K}^+]_o$ were increased to 150 mM?

POINTS TO PONDER

(Explanations on pp. A-37)

- The poison *cyanide* acts by binding irreversibly to one component of the electron transport chain, blocking its action. As a result, the entire electron-transport process comes to a screeching halt, and the cells lose more than 94 percent of their ATP-producing capacity. Considering the types of cell activities that depend on energy expenditure, what would be the consequences of cyanide poisoning?
- Why do you think a person is able to only briefly perform anaerobic exercise (such as lifting and holding a heavy weight) but can sustain aerobic exercise (such as walking or swimming) for long periods? (*Hint*: Muscles have limited energy stores.)
- Which of the following methods of transport is being used to transfer the substance into the cell in Figure 2-49?
 - diffusion down a concentration gradient
 - osmosis
 - facilitated diffusion
 - active transport
 - vesicular transport
 - It is impossible to tell from the information provided.

FIGURE 2-49 Concentration of substance

- Colostrum, the first milk that a mother produces, contains an abundance of antibodies, large protein molecules. These maternal antibodies help protect breastfed infants from infections until they are capable of producing their own antibodies. By what means do

you suspect these maternal antibodies are transported across the cells lining a newborn's digestive tract into the bloodstream?

5. Which of the following would occur if a neuron were experimentally stimulated simultaneously at both ends?
 - a. The action potentials would pass in the middle and travel to the opposite ends.
 - b. The action potentials would meet in the middle and then be propagated back to their starting positions.
 - c. The action potentials would stop as they meet in the middle.
 - d. The stronger action potential would override the weaker action potential.
 - e. Summation would occur when the action potentials meet in the middle, resulting in a larger action potential.
6. Compare the expected changes in membrane potential of a neuron stimulated with a *subthreshold stimulus* (a stimulus not sufficient to bring a membrane to threshold), a *threshold stimulus* (a stimulus just sufficient to bring the membrane to threshold), and a *suprathreshold stimulus* (a stimulus larger than that necessary to bring the membrane to threshold).

Assume you touched a hot stove with your finger. Contraction of the biceps muscle causes flexion (bending) of the elbow, whereas contraction of the triceps muscle causes extension (straightening) of the elbow. What pattern of postsynaptic potentials (EPSPs and IPSPs) do you expect would be initiated as a reflex in the cell bodies of the neurons controlling these muscles to pull your hand away from the painful stimulus?

7. Now assume your finger is being pricked to obtain a blood sample. The same *withdrawal reflex* would be initiated. What pattern of postsynaptic potentials would you voluntarily produce in the neurons controlling the biceps and triceps to keep your arm extended in spite of the painful stimulus?
8. Assume presynaptic excitatory neuron A terminates on a postsynaptic cell near the axon hillock and presynaptic excitatory neuron B terminates on the same postsynaptic cell on a dendrite located on the side of the cell body opposite the axon hillock. Explain why rapid firing of presynaptic neuron A could bring the postsynaptic neuron to threshold through temporal summation, thus initiating an action potential, whereas firing of presynaptic neuron B at the same frequency and the same magnitude of EPSPs may not bring the postsynaptic neuron to threshold.

CLINICAL CONSIDERATION

(Explanation on p. A-37)

When William H. was helping victims following a devastating earthquake in a region that was not prepared to swiftly set up adequate temporary shelter, he developed severe diarrhoea. He was diagnosed as having cholera, a disease transmitted through unsanitary water supplies that have been contaminated by fecal material from infected individuals. In this condition, the

toxin produced by the cholera bacteria leads to opening of the Cl^- channels in the luminal membranes of the intestinal cells, thereby increasing the secretion of Cl^- from the cells into the intestinal tract lumen. By what mechanisms would Na^+ and water be secreted into the lumen in accompaniment with Cl^- secretion? How does this secretory response account for the severe diarrhoea that is characteristic of cholera?

Body Systems

Body systems maintain homeostasis

Central nervous system

Cells make up body systems

Homeostasis

To maintain homeostasis, cells must work together in a coordinated fashion toward common goals. The two major regulatory systems of the body that help ensure life-sustaining coordinated responses are the nervous and endocrine systems.

Homeostasis is essential for survival of cells

To maintain homeostasis, cells must work together in a coordinated fashion toward a common purpose.

The nervous system is one of the two major regulatory systems of the body; the other is the endocrine system. A complex interactive network of three basic functional types of nerve cells—afferent neurons, efferent neurons, and interneurons—constitutes the excitable cells of the nervous system.

The central nervous system (CNS) consists of the brain and spinal cord, which receive input about the external and internal

environments from the afferent neurons. The CNS sorts and processes this input, then transmits appropriate directions to the efferent neurons, which carry the instructions to glands or muscles to bring about the desired response—some type of secretion or movement. Many of these neurally controlled activities are directed toward maintaining homeostasis. In general, the nervous system acts by means of its electrical signals (action potentials) to control the rapid responses of the body.

The **nervous system** is a complex system with two primary divisions, the central nervous system and the peripheral nervous system. The central nervous system is the focus of this chapter and builds on the principal function of the nervous system, communication, which was introduced in Chapter 2.

Clinical Connections

Jackie is a 40-year-old Caucasian woman. She is married, has two children, full-time employment, and enjoys a very active lifestyle. Over the past several months she has progressively been feeling more tired and occasionally noticed that she doesn't seem as strong as she once did. At work, she also noticed that she just didn't seem to be as mentally sharp as she used to be and started having some vision problems. She attributed these symptoms to just getting older. Her symptoms gradually worsened and started to include occasional loss of bladder control. Not until her family noticed her speech was slurred did she seek medical help. Fearing that she may have had a stroke, she went to her local emergency room.

She underwent a medical resonance imaging (MRI) test, and the results showed that although she did not have a stroke, there were several areas of scar tissue in her brain. After additional MRIs were done, more of these lesions were found in her spinal cord. Then a sample of cerebrospinal fluid was taken, and she was diagnosed with multiple sclerosis, an immune disease that affects the central nervous system.

3.1 Organization of the Nervous System

The central nervous system and the peripheral nervous system

The nervous system is organized into the **central nervous system (CNS)**, consisting of the brain and spinal cord, and the **peripheral nervous system (PNS)**, consisting of nerve fibres that carry information between the CNS and other parts of the body (the periphery) (► Figure 3-1).

The PNS is further subdivided into afferent and efferent divisions. The **afferent division** carries information to the CNS, informing it of changes in the external environment (e.g., ambient temperature) and internal environment (e.g., hunger). The **efferent division** communicates instructions from the CNS to **effector organs**—the muscles or glands that carry out the instructions to bring about the desired effect. The efferent nervous system has two subdivisions: the somatic and autonomic nervous systems. The **somatic nervous system** consists of the nerve fibres of the motor neurons that supply the skeletal muscles.

The **autonomic nervous system (ANS)** consists of nerve fibres that innervate smooth muscle, cardiac muscle, and glands. The ANS is further subdivided into the **sympathetic nervous system** and the **parasympathetic nervous system**, both of which innervate most of the organs supplied by the autonomic system.

Recognize that all these types of nervous systems refer to subdivisions of a single integrated system. Each subdivision is based on differences in the structure, location, and functions of the various diverse parts of the whole nervous system.

Three functional classes of neurons

Three functional classes of neurons make up the nervous system: *afferent neurons*, *efferent neurons*, and *interneurons*. The afferent division of the peripheral nervous system consists of afferent neurons, which are shaped quite differently from efferent neurons and interneurons (► Figure 3-2). At its peripheral ending, a typical afferent neuron has a **sensory receptor** that generates action potentials in response to a particular type of stimulus (e.g., touch). (Do not confuse this type of stimulus-sensitive afferent receptor with the protein receptors on all cell surfaces that bind chemical

► FIGURE 3-1 Organization of the nervous system

► FIGURE 3-2 Structure and location of the three functional classes of neurons

messengers.) The afferent neuron cell body, which is devoid of dendrites and presynaptic inputs, is located adjacent to the spinal cord. A long *peripheral axon*, commonly called the *afferent fibre*, extends from the receptor to the cell body, and a short *central axon* passes from the cell body into the spinal cord. Action potentials are initiated at the receptor (distal end) of the peripheral axon in response to a stimulus and are propagated along the peripheral axon and central axon toward the spinal cord (proximal end). The terminals of the central axon diverge and synapse with other neurons within the spinal cord, thus disseminating information about the stimulus. Afferent neurons lie primarily within the PNS, and only a small portion of their central axon endings project into the spinal cord and relay peripheral signals.

Efferent neurons also lie primarily in the peripheral nervous system (Figure 3-2). Their cell bodies originate in the CNS, where many centrally located presynaptic inputs converge on them to influence their outputs to the effector organs. Efferent axons (efferent fibres) travel out of the CNS to meet the muscles or glands they innervate. They convey their integrated output for the effector organs to put into effect. (An autonomic nerve pathway consists of a two-neuron chain between the CNS and the effector organ.)

Interneurons lie entirely within the CNS. About 99 percent of all neurons belong to this category. The human CNS is estimated to have more than 100 billion interneurons! These neurons serve two main roles. First, as their name implies, they lie between the afferent and efferent neurons (connectors) and are important in integrating peripheral responses to peripheral information (*inter* means “between”). For example, on receiving information through afferent neurons that you are touching a hot object,

appropriate interneurons signal efferent neurons that transmit to your hand and arm muscles the message “Pull the hand away from the hot object!” The more complex the required action, the greater the number of interneurons interposed between the afferent message and the efferent response. Second, interconnections between interneurons themselves are responsible for abstract phenomena associated with the mind, such as thoughts, emotions, memory, creativity, intellect, and motivation. These activities are the least understood functions of the nervous system.

With this brief introduction to the types of neurons and their location in the various divisions of the nervous system, we now turn our attention to the CNS.

3.2 | Structure and Function of the Central Nervous System

The central nervous system consists of the brain and spinal cord. The estimated 100 billion neurons in your brain are assembled into complex networks that enable you to (1) subconsciously regulate your internal environment by neural means, (2) experience emotions, (3) voluntarily control your movements, (4) perceive (be consciously aware of) your own body and your surroundings, and (5) engage in other higher cognitive processes, such as thought and memory. The term **cognition** refers to the act or process of knowing, including both awareness and judgment.

No part of the brain acts in isolation from other brain regions, because networks of neurons are anatomically linked by synapses, and neurons throughout the brain communicate extensively with each other by electrical and chemical means. However, neurons that work together to ultimately accomplish a given function tend to be organized within a discrete location. Thus, although the brain functions as a whole, it is organized into different regions. The parts of the brain can be arbitrarily grouped in various ways based on anatomical distinctions, functional specialization, and evolutionary development. In this text we use the following grouping (see ■ Table 3-1):

1. Brain stem
2. Cerebellum
3. Forebrain
 - a. Diencephalon
 - (1) Hypothalamus
 - (2) Thalamus
 - b. Cerebrum
 - (1) Basal ganglia
 - (2) Cerebral cortex

■ TABLE 3-1 Overview of Structures and Functions of the Major Components of the Brain

3

© 2016 Cengage

The order in which these components are listed generally represents both their anatomic location (from bottom to top) and their complexity and sophistication of function (from the least specialized, oldest level to the newest, most specialized level).

A primitive nervous system consists of comparatively few interneurons interspersed between afferent and efferent neurons. During evolutionary development, the interneuronal component progressively expanded, formed more complex interconnections, and became localized at the head end of the nervous system, forming the brain. Newer, more sophisticated layers of the brain were added on to the older, more primitive layers. The human brain represents the present peak of development.

The *brain stem*, the oldest region of the brain, is continuous with the spinal cord (Table 3-1; and see Figure 3-21b). It consists of the midbrain, pons, and medulla. The brain stem controls many of the life-sustaining processes, such as respiration, circulation, and digestion, which are common to many of the lower vertebrate forms. These processes are often referred to as *vegetative functions*, meaning functions performed unconsciously, as

the person has no awareness or control. When a person loses higher brain functions, these lower brain levels—in accompaniment with appropriate supportive therapy, such as adequate nourishment—can still sustain the functions essential for survival.

Attached to the top rear portion of the brain stem is the *cerebellum*, which is concerned with maintaining proper position of the body in space (proprioception; p. 117) and subconscious coordination of motor activity (movement). The cerebellum also plays a key role in learning skilled motor tasks, such as a dance routine.

On top of the brain stem, tucked within the interior of the cerebrum, is the *diencephalon*. It houses two brain components: the *hypothalamus*, which controls many homeostatic functions important in maintaining stability of the internal environment; and the *thalamus*, which performs some primitive sensory processing.

On top of the lower brain regions is the **cerebrum**. The cerebrum is progressively larger and more highly convoluted (i.e., it has tortuous ridges delineated by deep grooves or folds) in the

3.3 | Protection of the Central Nervous System

Major Functions

1. Sensory perception
 2. Voluntary control of movement
 3. Language
 4. Personality traits
 5. Sophisticated mental events, such as thinking, memory, decision making, creativity, and self-consciousness
1. Inhibition of muscle tone
 2. Coordination of slow, sustained movements
 3. Suppression of useless patterns of movement
1. Relay station for all synaptic input
 2. Crude awareness of sensation
 3. Some degree of consciousness
 4. Role in motor control
1. Regulation of many homeostatic functions, such as temperature control, thirst, urine output, and food intake
 2. Important link between nervous and endocrine systems
 3. Extensive involvement with emotion and basic behavioural patterns
 4. Role in sleep–wake cycle
1. Maintenance of balance
 2. Enhancement of muscle tone
 3. Coordination and planning of skilled voluntary muscle activity
1. Origin of majority of peripheral cranial nerves (midbrain, pons, and medulla)
 2. Cardiovascular, respiratory, and digestive control centres
 3. Regulation of muscle reflexes involved with equilibrium and posture
 4. Reception and integration of all synaptic input from spinal cord; arousal and activation of cerebral cortex
 5. Role in sleep–wake cycle

more advanced vertebrate species. The cerebrum is most highly developed in humans, where it constitutes about 80 percent of the total brain weight. The outer layer of the cerebrum is the highly convoluted *cerebral cortex*, which caps an inner core that houses the *basal ganglia*. The myriad convolutions of the human cerebral cortex give it the appearance of a much-folded walnut (see Figure 3-21a). In many lower mammals, the cortex is perfectly smooth. Without these surface wrinkles, the human cortex would take up to three times the area it does, and, accordingly, would not fit like a cover over the underlying structures. The increased neural circuitry housed in the extra cerebral cortical area not found in lower species is responsible for many of our unique human abilities. The cerebral cortex plays a key role in the most sophisticated neural functions, such as voluntary initiation of movement, fine sensory perception, conscious thought, language, personality traits, and other factors we associate with the mind or intellect. It is the highest, most complex, integrating area of the brain.

Before we describe each region of the CNS in detail, we are going to look at how the brain is protected and nourished.

Glial cells

About 90 percent of the cells within the CNS are not neurons but **glial cells**, or **neuroglia**. Despite their large numbers, glial cells occupy only about half the volume of the brain, because they do not branch as extensively as neurons do.

Unlike neurons, glial cells do not initiate or conduct nerve impulses. However, they do communicate with neurons and among themselves by means of chemical signals, and they maintain homeostasis within the nervous system. *Glia* means “glue,” and since the discovery of glial cells in the 19th century, scientists thought of these cells as passive “mortar” that physically supported the functionally important neurons. In the last decade the roles of these dynamic cells have become apparent. Glial cells serve as the connective tissue of the CNS and, as such, help support the neurons both physically and metabolically. They homeostatically maintain the composition of the specialized extracellular environment surrounding the neurons within the narrow limits optimal for normal neuronal function. Furthermore, they actively modulate synaptic function and are now considered nearly as important as neurons to learning and memory. We now look at the specific roles of the four major types of glial cells in the CNS: *astrocytes*, *oligodendrocytes*, *microglia*, and *ependymal cells* (► Figure 3-3 and ■ Table 3-2).

Astrocytes

Named for their starlike shape (*astro* means “star”; *cyte* means “cell”) (► Figure 3-4), **astrocytes** are the most abundant glial cells. They fulfill seven critical functions:

1. As the main connective tissue of the CNS, astrocytes hold the neurons together in proper spatial relationships.
2. Astrocytes serve as a scaffold to guide neurons to their proper final destination during fetal brain development.
3. These glial cells induce the small blood vessels of the brain to undergo the anatomic and functional changes that are responsible for establishing the blood–brain barrier, a highly selective barricade between the blood and brain that we will soon describe in greater detail.
4. Astrocytes are important in the repair of brain injuries and in neural scar formation.
5. They play a role in neurotransmitter activity. Astrocytes take up and degrade glutamate and gamma-aminobutyric acid (GABA), excitatory and inhibitory neurotransmitters, respectively, thus bringing the actions of these chemical messengers to a halt.
6. Astrocytes take up excess K^+ from the brain ECF when high action potential activity outpaces the ability of the K^+ pump to return the effluxed K^+ to the neurons. (Recall that K^+ leaves a neuron during the falling phase of an action potential; p. 63) By taking up excess K^+ , astrocytes help maintain the proper brain–ECF ion concentration to sustain

► **FIGURE 3-3 Glial cells of the central nervous system.** The glial cells include the astrocytes, oligodendrocytes, microglia, and ependymal cells.

■ **TABLE 3-2 Functions of Glial Cells**

Type of Glial Cell	Functions
Astrocytes	Physically support neurons in proper spatial relationships Serve as a scaffold during fetal brain development Induce formation of blood–brain barrier Form neural scar tissue Take up and degrade released neurotransmitters into raw materials for synthesis of more neurotransmitters by neurons Take up excess K^+ to help maintain proper brain–ECF ion concentration and normal neural excitability Enhance synapse formation and strengthen synaptic transmission via chemical signalling with neurons
Oligodendrocytes	Form myelin sheaths in CNS
Microglia	Play a role in defence of brain as phagocytic scavengers
Ependymal cells	Line internal cavities of brain and spinal cord Contribute to formation of cerebrospinal fluid Serve as neural stem cells with the potential to form new neurons and glial cells

Astrocyte

► **FIGURE 3-4 Astrocytes.** Note the starlike shape of these astrocytes, which have been grown in tissue culture.

normal neural excitability. If K^+ levels in the brain ECF were allowed to rise, the resultant lower K^+ concentration gradient between the neuronal ICF and surrounding ECF would reduce the neuronal membrane closer to threshold, even at rest. This would increase the excitability of the brain. In fact, an elevation in brain–ECF K^+ concentration may be one of the factors responsible for the brain cells’ explosive convulsive discharge that occurs during epileptic seizures.

1. In recent discoveries, astrocytes along with other glial cells are now known to enhance synapse formation and to modify synaptic transmission. Astrocytes communicate with neurons and with one another by means of chemical signals in two ways. First, gap junctions (pp. 34–35) have been identified between the astrocytes themselves and between astrocytes and neurons. Chemical signals can pass directly between cells through these small connecting tunnels without entering the surrounding ECF. Second, astrocytes have receptors for the neurotransmitter glutamate released by neurons. Furthermore, the firing of neurons in the brain in some instances triggers the release of ATP along with glutamate from the axon terminal. Binding of glutamate to an astrocyte’s receptors and/or detection of extracellular ATP by the astrocyte leads to K^+ influx into this glial cell. The resultant rise in intracellular K^+ prompts the astrocyte itself to release ATP, thereby activating adjacent glial cells. In this way, astrocytes share information about action potential activity in a nearby neuron. Thus, astrocytes can communicate among themselves by means of coupling of the astrocytes at gap junctions and by K^+ wave propagation. Astrocytes and other glial cells can also release

the same neurotransmitters as neurons do, as well as other chemical signals. These extracellular chemical signals released by glial cells can affect neuronal excitability and strengthen synaptic activity, such as by increasing neuronal release of a neurotransmitter or promoting the formation of new synapses. Glial modulation of synaptic activity is likely important in memory and learning. Scientists are trying to sort out the two-directional chatter that takes place between and among the glial cells and neurons, because this dialogue plays an important role in the processing of information in the brain.

Some neuroscientists believe that synapses should be considered “three-party” junctures involving the glial cells as well as the traditional synapse members, the presynaptic and postsynaptic neurons. This point of view is indicative of the increasingly important role being placed on astrocytes in synapse function.

Oligodendrocytes

As mentioned in Chapter 2 (p. 70), oligodendrocytes form the insulating myelin sheaths around axons in the CNS. An oligodendrocyte has several elongated projections, each of which is wrapped jelly-roll fashion around a section of an interneuronal axon to form a patch of myelin (see ► Figures 2-43b and 3-3).

Clinical Connections

Multiple sclerosis is a chronic disease that leads to nerve damage in the brain, spinal cord, and optic nerves. It is an immune disease and causes inflammation that destroys the myelin of neurons and leaves the scar tissue that can be seen on an MRI. Recall from Chapter 2 that signal conduction in nerves is affected by myelin. The pattern of demyelination is not the same in all patients. Demyelination can occur in different nerves, and this leads to the variable symptoms of multiple sclerosis.

Microglia

Microglia are the immune cells of the CNS. These scavengers are “cousins” of monocytes, a type of white blood cell that leaves the blood and sets up residence as a front-line defence agent (i.e., has innate immunity) in various tissues throughout the body. Microglia are derived from bone marrow tissue that gives rise to monocytes. During embryonic development, microglia migrate to the CNS, where they remain stationary until activated by an infection or injury.

In the resting state, microglia are wispy cells with many long branches that radiate outward. Resting microglia don’t just watch and wait until activated, they also release low levels of growth factors, such as *nerve growth factor*, that help neurons and other glial cells survive and thrive. When trouble occurs in the CNS, microglia retract their branches, round up, and become highly mobile, moving toward the affected area to remove any foreign invaders or tissue debris. Activated microglia release destructive chemicals for assault against their target.

Researchers increasingly suspect that excessive release of these chemicals from overzealous microglia may damage the neurons they are meant to protect, thereby

contributing to the insidious neuronal damage seen in stroke, Alzheimer's disease, multiple sclerosis, dementia (mental failing) in AIDS patients, and other *neurodegenerative diseases*.

Ependymal cells

Ependymal cells line the internal, fluid-filled cavities of the CNS. As the nervous system develops embryonically from a hollow neural tube, the original central cavity of this tube is maintained and modified to form the ventricles and central canal. The **ventricles**, which consist of four interconnected chambers within the interior of the brain, are continuous with the narrow, hollow **central canal** that tunnels through the middle of the spinal cord (► Figure 3-5). The ependymal cells lining the ventricles help form the cerebrospinal fluid that surrounds and cushions the brain and spinal cord (a topic to be discussed shortly). Ependymal cells are one of the few cell types to bear cilia: short, brushlike projections from the cell surface, which are continuous with the cell's surface membrane and beat rhythmically back and forth. Microtubules inside the cilia provide the structure as well as the rhythmic movement driven by the protein dynein. Beating of ependymal cilia contributes to the flow of cerebrospinal fluid throughout the ventricles.

New research has identified a different role for the ependymal cells. According to Dr. Jonas Frisén and colleagues, these cells serve as neural stem cells with the potential of forming not only other glial cells but new neurons as well. The traditional view has long held that new neurons are not produced in the mature brain. Then, in the late 1990s, scientists discovered that new neurons are produced in one restricted site: namely, a specific part of the hippocampus, a structure important for learning and memory (p. 126). Neurons in the rest of the brain are considered irreplaceable. But the discovery that ependymal cells are precursors for new neurons suggests that the adult brain has more potential for repairing damaged regions than previously assumed. Currently, there is no evidence that the brain spontaneously repairs itself following neuron-losing insults, such as head trauma, strokes, and neurodegenerative disorders. Apparently, most brain regions cannot activate this mechanism for replenishing neurons, probably because the appropriate “cocktail” of supportive chemicals is not present.

► FIGURE 3-5 The ventricles of the brain

Researchers hope that probing into why these ependymal cells are dormant and how they might be activated will lead to the possibility of unlocking the brain's latent capacity for self-repair.

Unlike neurons, glial cells do not lose the ability to undergo cell division, so most brain tumours of neural origin consist of glial cells (glial tumours or **gliomas**). Neurons themselves do not form tumours because they are unable to divide and multiply. Brain tumours of non-neural origin are of two types: (1) those that metastasize (spread) to the brain from other sites; and (2) **meningiomas**, which originate from the meninges, the protective membranes covering the CNS. We are next going to examine the meninges and other means by which the CNS is protected.

Check Your Understanding 3.1

1. Draw a flow diagram showing the organization of the subdivisions of the human nervous system.
2. Compare the structure, location, and function of the functional classes of neurons. Do the same for glial cells.

Protection of the delicate central nervous tissue

Central nervous tissue is very delicate. This characteristic, coupled with the fact that damaged nerve cells cannot be replaced, makes it imperative that this fragile, irreplaceable tissue be well protected. Four major features help protect the CNS from injury:

1. Hard, bony structures enclose the CNS; the *cranium* (skull) encases the brain, and the *vertebral column* surrounds the spinal cord.
2. Three protective and nourishing membranes, the *meninges*, lie between the bony covering and the nervous tissue.
3. The brain “floats” in a special cushioning fluid, the *cerebrospinal fluid* (CSF).
4. A highly selective *blood–brain barrier* limits the access of blood-borne materials into the vulnerable brain tissue.

The role of the first of these protective devices, the bony covering, is self-evident. The latter three protective mechanisms warrant further discussion.

Meningeal membranes: Wrapping, protecting, and nourishing

The **meninges**—three membranes that wrap the CNS—are, from the outermost to the innermost layer, the *dura mater*, the *arachnoid mater*, and the *pia mater* (► Figure 3-6). (*Mater* means “mother,” indicative of the protective and supportive role of these membranes.)

The **dura mater** is a tough, inelastic covering consisting of two layers (*dura* means “tough”). Usually, these layers adhere closely, but in some regions they are separated to form blood-filled cavities, **dural sinuses**, or, in the case of the larger cavities, **venous sinuses**. Venous blood draining from the brain empties into these sinuses to be returned to the heart. Cerebrospinal fluid also re-enters the blood at one of these sinus sites.

(a) Sagittal section of brain and spinal cord

Cerebrospinal fluid

- 1** is produced by the choroid plexuses,
- 2** circulates throughout the ventricles,
- 3** exits the fourth ventricle at the base of the brain,
- 4** flows in the subarachnoid space between the meningeal layers, and
- 5** is finally reabsorbed from the subarachnoid space into the venous blood across the arachnoid villi.

© 2016 Cengage

FIGURE 3-6 Relationship of the meninges and cerebrospinal fluid to the brain and spinal cord. (a) Brain, spinal cord, and meninges in sagittal section. The arrows and squared numbers with accompanying explanations indicate the direction of flow of cerebrospinal fluid (in yellow). (b) Frontal section in the region between the two cerebral hemispheres of the brain, depicting the meninges in greater detail

The **arachnoid mater** gets its name from the cobweb appearance of this delicate, richly vascularized layer (*arachnoid* means “spider-like”). The space between the arachnoid layer and the underlying pia mater, the **subarachnoid space**, is filled with CSF. Protrusions of arachnoid tissue, the **arachnoid villi**, penetrate through gaps in the overlying dura and project into the dural sinuses. CSF is reabsorbed across the surfaces of these villi into the blood circulating within the sinuses.

The innermost meningeal layer, the **pia mater**, is the most fragile (*pia* means “gentle”). It is highly vascular and closely adheres to the surfaces of the brain and spinal cord, following every ridge and valley. In certain areas it dips deeply into the brain to bring a rich blood supply into close contact with the ependymal cells lining the ventricles. This relationship is important in the formation of CSF, the topic we turn to now.

Cerebrospinal fluid: A cushion for the brain

Cerebrospinal fluid (CSF) surrounds and cushions the brain and spinal cord. The CSF has about the same density as the brain itself, so the brain essentially floats, or is suspended, in this special fluid environment. The major function of CSF is to serve as a shock-absorbing fluid to prevent the brain from bumping against the interior of the hard skull when the head is subjected to sudden, jarring movements.

In addition to protecting the delicate brain from mechanical trauma, the CSF plays an important role in the exchange of materials between the neural cells and the surrounding interstitial fluid. The brain interstitial fluid—not the blood or CSF—comes into direct contact with the neurons and glial cells. Because the brain interstitial fluid directly bathes the neural cells, its composition is critical. The composition of the brain interstitial fluid is influenced more by changes in the composition of the CSF than by alterations in the blood. Accordingly, the CSF’s composition must be carefully regulated.

Cerebrospinal fluid is formed primarily by the **choroid plexuses** found in particular regions of the ventricle cavities of the brain. Choroid plexuses consist of richly vascularized, cauliflower-like masses of pia mater tissue that dip into pockets formed by ependymal cells. Cerebrospinal fluid is formed as a result of selective transport mechanisms across the membranes of the choroid plexuses. The composition of CSF differs from that of plasma. For example, CSF is lower in K^+ and higher in K^+ , thus making the brain interstitial fluid an ideal environment for the movement of these ions down concentration gradients, a process essential for conduction of nerve impulses (p. 34).

Once CSF is formed, it flows through the four interconnected ventricles within the interior of the brain and through the spinal cord’s narrow central canal, which is continuous with the last ventricle. Cerebrospinal fluid escapes through small openings from the fourth ventricle at the base of the brain, enters the subarachnoid space, and subsequently flows between the meningeal layers over the entire surface of the brain and spinal cord (see ▶ Figure 3-6). When the CSF reaches the upper regions of the brain, it is reabsorbed from the subarachnoid space into the venous blood through the arachnoid villi.

Flow of CSF through this system is facilitated by ciliary beating along with circulatory and postural factors that result in a CSF pressure of about 10 mmHg. Reduction of this pressure by

removal of even a few millilitres of CSF during a spinal tap for laboratory analysis may produce severe headaches.

Through the ongoing processes of formation, circulation, and reabsorption, the entire CSF volume of about 125–150 mL is replaced more than three times a day. If any one of these processes is defective so that excess CSF accumulates, **hydrocephalus** (“water on the brain”) occurs. The resulting increase in CSF pressure can lead to brain damage and mental retardation if untreated. Treatment consists of surgically shunting the excess CSF to veins elsewhere in the body.

Clinical Connections

In many diseases that affect the CNS, the CSF can sometimes be used for diagnostic testing, which explains why Jackie’s CSF was sampled after doctors identified multiple lesions in her brain and spinal cord. In her case, the CSF was clear and colourless and had normal cell counts, indicating there was no active inflammation, as might be seen in other CNS diseases, such as meningitis. However, in the case of multiple sclerosis—although the CSF visually appears normal—the CSF frequently has elevated levels of the antibody IgG, compared to IgG levels in the blood (see Chapter 11, p. 475). This is a sign that a recurring immunological response has occurred.

The blood–brain barrier

The brain is carefully shielded from harmful changes in the blood by a highly selective **blood–brain barrier (BBB)** consisting of endothelial cells. Throughout the body, exchange of materials between blood and surrounding interstitial fluid can take place only across the walls of capillaries. Unlike the rather free exchange across capillaries elsewhere, permissible exchanges across brain capillaries are strictly limited. Changes in most plasma constituents do not easily influence the composition of brain interstitial fluid, as only carefully regulated exchanges can be made across the BBB. For example, even if the K^+ level in the blood is doubled, little change occurs in the K^+ concentration of the fluid bathing the central neurons. This is beneficial because alterations in interstitial fluid K^+ would be detrimental to neuronal function.

The BBB consists of both anatomic and physiological factors. Capillary walls throughout the body are formed by a single layer of cells. Usually, all plasma components (except the large plasma proteins) can be freely exchanged between the blood and the surrounding interstitial fluid through holes or pores between the cells making up the capillary wall. In brain capillaries, however, the cells are joined by *tight junctions* (p. 34), which completely seal the capillary wall so that nothing can be exchanged across the wall by passing between the cells. The only possible exchanges are through the capillary cells themselves. Lipid-soluble substances, such as oxygen, carbon dioxide, alcohol, and steroid hormones, penetrate these cells easily by dissolving in their lipid plasma membrane. Small water molecules also diffuse through readily, apparently by passing between the phospholipid molecules that compose the plasma membrane. All other substances exchanged between the blood and brain interstitial fluid—including such essential materials as glucose, amino acids, and ions—are transported by highly selective membrane-bound carriers. Therefore, transport

across brain capillary walls *between* the wall-forming cells is *anatomically prevented*, and transport *through* the cells is *physiologically restricted*. Together, these mechanisms constitute the BBB.

By strictly limiting exchange between the blood and the brain, the BBB protects the delicate brain from chemical fluctuations in the blood and minimizes the possibility that potentially harmful blood-borne substances might reach the central neural tissue. It further prevents certain circulating hormones that could also act as neurotransmitters from reaching the brain, where they could produce uncontrolled nervous activity. On the negative side, the BBB limits the use of drugs for the treatment of brain and spinal cord disorders, because many drugs are unable to penetrate this barrier.

Brain capillaries are surrounded by astrocyte processes, which at one time were erroneously thought to be physically responsible for the BBB. Scientists now know that astrocytes have two roles regarding the BBB: (1) They signal the cells forming the brain capillaries to “get tight.” Capillary cells do not have an inherent ability to form tight junctions; they do so only at the command of a signal within their neural environment. (2) Astrocytes participate in the cross-cellular transport of some substances such as K^+ .

For functional reasons, certain areas of the brain called the **circumventricular organs** are not subject to the BBB. The lack of a BBB in these areas allows these organs to “sample” the blood and adjust their output accordingly to maintain homeostasis. Part of this output is in the form of hormones that must enter the capillaries to be transported to their sites of action. Appropriately, these capillaries are not sealed by tight junctions.

The role of oxygen and glucose

Even though many substances in the blood never actually come in contact with the brain tissue, the brain, more than any other tissue, is highly dependent on a constant blood supply. Unlike most tissues, which can resort to anaerobic metabolism to produce ATP in the absence of oxygen for at least short periods (p. 28), the brain cannot produce ATP in the absence of oxygen. Scientists recently discovered an oxygen-binding protein, **neuroglobin**, in the brain. This molecule is similar to haemoglobin, the oxygen-carrying protein in red blood cells (p. 436), and is thought to play a key role in oxygen handling in the brain, although its exact function remains to be determined. As well, in contrast to most tissues, which can use other sources of fuel for energy production in lieu of glucose, the brain normally uses only glucose, but does not store any of this nutrient. Therefore, the brain absolutely depends on a continuous, adequate blood supply of oxygen and glucose.

Clinical Note Brain damage results if this organ is deprived of its critical oxygen supply for approximately 5 minutes or if its glucose supply is cut off for more than 15 minutes. The most common cause of inadequate blood supply to the brain is a stroke. (See Concepts, Challenges, and Controversies for details.)

1. Name the meninges, from outermost to innermost.
2. Explain how the blood-brain barrier anatomically prevents transport between the cells that form the walls of brain capillaries and physiologically restricts transport through these cells.

3.4 | Spinal Cord

The **spinal cord** is a long, slender cylinder of nerve tissue that extends from the brain stem. It is about 45 cm long and 2 cm in diameter (about the size of your thumb), and is protected by the vertebral column.

The vertebral canal

Exiting through a large hole in the base of the skull, the spinal cord descends through the vertebral canal and is surrounded by the vertebral column (► Figure 3-7). Paired **spinal nerves** emerge from the spinal cord through spaces formed between the bony, winglike arches (pedicle and lamina) of adjacent vertebrae. The spinal nerves are named according to the region of the vertebral column from which they originate (► Figure 3-8): there are eight pairs of *cervical* (neck) nerves (namely C1–C8), twelve *thoracic* (chest) nerves, five *lumbar* (abdominal) nerves, five *sacral* (pelvic) nerves, and one *coccygeal* (tailbone) nerve.

During development, the vertebral column grows about 25 cm longer than the spinal cord. Because of this differential

► FIGURE 3-7 Location of the spinal cord relative to the vertebral column

► **FIGURE 3-8 Spinal nerves.** There are 31 pairs of spinal nerves named according to the region of the vertebral column from which they emerge. Because the spinal cord is shorter than the vertebral column, spinal nerve roots must descend along the cord before emerging from the vertebral column at the corresponding intervertebral space, especially those beyond the level of the first lumbar vertebra (L1). Collectively these rootlets are called the **cauda equina**, literally, horse's tail. (a) Posterior view of the brain, spinal cord, and spinal nerves (on the right side only). (b) Lateral view of the spinal cord and spinal nerves emerging from the vertebral column

growth, segments of the spinal cord that give rise to various spinal nerves are not aligned with the corresponding intervertebral spaces. Most spinal nerve roots must descend along the cord before emerging from the vertebral column at the corresponding space. The spinal cord itself extends only to the level of the first or second lumbar vertebra (about waist level), so the nerve roots of the remaining nerves are greatly elongated, to exit the vertebral column at their appropriate space. The thick bundle of elongated nerve roots within the lower vertebral canal is called the **cauda equina** (horse's tail) because of its appearance (Figure 3-8b).

Spinal taps to obtain a sample of CSF are performed by inserting a needle into the vertebral canal below the level of

the second lumbar vertebra. Insertion at this site does not run the risk of penetrating the spinal cord. The needle pushes aside the nerve roots of the cauda equina so that a sample of the surrounding fluid can be withdrawn safely.

Spinal cord white matter

Although there are some slight regional variations, the cross-sectional anatomy of the spinal cord is generally the same throughout its length (► Figure 3-9). In contrast to the grey matter forming an outer shell that caps an inner white core in the brain, the grey matter in the spinal cord forms an inner butterfly-shaped region surrounded by the outer white matter. The cord **grey matter**

consists primarily of neuronal cell bodies and their dendrites, short interneurons, and glial cells. The **white matter** is organized into tracts, which are bundles of nerve fibres (axons of long interneurons) with a similar function. The bundles are grouped into columns that extend the length of the cord. Each of these tracts begins or ends within a particular area of the brain, and each transmits a specific type of information. Some are **ascending tracts** (cord to brain) that transmit to the brain signals derived from afferent input. Others are **descending tracts** (brain to cord) that relay messages from the brain to efferent neurons (▶ Figure 3-10).

The tracts are generally named for their origin and termination. For example, the **ventral spinocerebellar tract** is an ascending pathway that originates in the spinal cord, runs up the ventral (toward the front) margin of the cord, with several synapses along the way, and eventually terminates in the cerebellum (▶ Figure 3-11a). This tract carries information—derived from muscle stretch receptors and delivered to the spinal cord by afferent fibres—for use by the spinocerebellum. In contrast, the **ventral corticospinal tract** is a descending pathway that originates in the motor region of the cerebral cortex, then travels down the ventral portion of the spinal cord, and terminates in the spinal cord on the cell bodies of efferent motor neurons supplying skeletal muscles (▶ Figure 3-11b). Because various types of signals are carried in different tracts within the spinal cord, damage to particular areas of the cord can interfere with some functions, whereas other functions remain intact.

Spinal cord grey matter

The centrally located grey matter is also functionally organized (▶ Figure 3-12). The central canal, which is filled with CSF, lies in the centre of the grey matter. Each half of the grey matter is divided into a **dorsal (posterior) horn**, a **ventral (anterior) horn**, and a **lateral horn**. The dorsal horn contains cell bodies of interneurons on which afferent neurons terminate. The ventral horn contains cell bodies of the efferent motor neurons supplying skeletal muscles. Autonomic nerve fibres supplying cardiac and smooth muscle and exocrine glands originate at cell bodies found in the lateral horn.

Spinal nerves

Spinal nerves connect with each side of the spinal cord by a **dorsal root** and a **ventral root** (see Figure 3-9). Afferent fibres carrying incoming signals from peripheral receptors enter the spinal cord through the dorsal root. The cell bodies for the afferent neurons at each level are clustered in a **dorsal root ganglion**. (Note that a collection of neuronal cell bodies located outside the CNS is called a *ganglion*, whereas a functional collection of cell bodies within the CNS is referred to as a *centre* or a *nucleus*.) The cell bodies for the efferent neurons originate in the grey matter and send axons out through the ventral root. Therefore, efferent fibres carrying outgoing signals to muscles and glands exit through the ventral root.

The dorsal and ventral roots at each level join to form a *spinal nerve* that emerges from the vertebral column (see Figure 3-9). A spinal nerve contains both afferent and efferent fibres that traverse between a particular region of the body and the spinal cord. Note the relationship between a *nerve* and a *neuron*. A **nerve** is a bundle of peripheral neuronal axons, some afferent and some efferent, enclosed by a covering of connective tissue

and following the same pathway (▶ Figure 3-13). A nerve does not contain a complete nerve cell, only the axonal portions of many neurons. (By this definition, there are no nerves in the CNS! Bundles of axons in the CNS are called *tracts*.) The individual fibres within a nerve generally do not have any direct influence on one another. They travel together for convenience, just as many individual telephone lines are carried within a telephone cable, yet any particular phone connection can be private without interference or influence from other lines in the cable.

The 31 pairs of spinal nerves, along with the 12 pairs of cranial nerves that arise from the brain, constitute the *peripheral nervous system*. After they emerge, the spinal nerves progressively branch to form a vast network of peripheral nerves that supply the tissues. Each segment of the spinal cord gives rise to a pair of spinal nerves that ultimately supply a particular region of the body with both afferent and efferent fibres. Consequently, the location and extent of sensory and motor deficits associated with spinal cord injuries can be clinically important in determining the level and extent of the cord injury.

Clinical Connections

In the case of Jackie, a patient with multiple sclerosis, several regions of scarring were seen in the spinal cord, and this provides an example of how sensory and motor defects can be identified. Jackie was experiencing muscle weakness and bladder-control problems that were due to an interruption of the nerve signals. In patients with multiple sclerosis, spinal cord lesions are frequently observed in the cervical, or neck, area, and these affect the corticospinal tract. What is different in multiple sclerosis compared to a trauma that severs the spinal cord is that afferent and efferent nerve signals still occur, but they are impaired.

With reference to sensory input, each specific region of the body surface supplied by a particular spinal nerve is called a **dermatome**. These same spinal nerves also carry fibres that branch off to supply internal organs, and sometimes pain originating from one of these organs is “referred” to the corresponding dermatome supplied by the same spinal nerve. **Referred pain** originating in the heart, for example, may appear to come from the left shoulder and arm. The mechanism responsible for referred pain is not completely understood. Inputs arising from the heart presumably share a pathway to the brain in common with inputs from the left, upper extremity. The higher perception levels, being more accustomed to receiving sensory input from the left arm than from the heart, may interpret the input from the heart as having arisen from the left arm.

Basic reflexes

The spinal cord is strategically located between the brain and the afferent and efferent fibres of the peripheral nervous system. This location enables the spinal cord to fulfill its two primary functions: (1) serving as a link for transmission of information between the brain and the remainder of the body, and (2) integrating reflex activity between afferent input and efferent output without involving the brain. This type of reflex activity is called a *spinal reflex*.

A **reflex** is any response that occurs automatically without conscious effort and is part of a biological control system that links stimulus and response. There are two types of reflexes: (1) **simple (basic) reflexes**, which are built-in, unlearned responses, such as pulling the hand away from a burning hot object; and (2) **acquired (conditioned) reflexes**, which are a result of practice and learning, such as a pianist striking a particular key upon seeing a certain note on a music staff. The musician reads music and plays it automatically, but only after considerable conscious training effort.

REFLEX ARC

The neural pathway involved in accomplishing reflex activity is known as a **reflex arc**, which typically includes five basic components:

1. Receptor
2. Afferent pathway
3. Integrating centre
4. Efferent pathway
5. Effector

► FIGURE 3-12 Regions of the grey matter

The receptor responds to a **stimulus**, which is a detectable physical or chemical change in the environment of the receptor. In response to the stimulus, the receptor produces an action potential that is relayed by the **afferent pathway** to the **integrating centre** for processing. Usually the integrating centre is the CNS. The spinal cord and brain stem integrate basic reflexes, whereas higher brain levels usually process acquired reflexes. The integrating centre processes all information available to it from this receptor as well as from all other inputs, then makes a decision about the appropriate response. The instructions from the integrating centre are transmitted via the **efferent pathway** to the effector—a muscle or gland—which carries out the desired response. Unlike conscious behaviour, in which any one of a number of responses is possible, a reflex response is predictable, because the pathway between the receptor and the effector is always the same.

STRETCH REFLEX

The **stretch reflex** involves an afferent neuron originating at a stretch-detecting receptor in a skeletal muscle. This afferent neuron terminates directly on the efferent neuron supplying the same skeletal muscle and, when activated, causes it to counteract the stretch by stimulating the muscle to contract. The stretch reflex is a **monosynaptic reflex** (one-synapse), because the only synapse in the reflex arc is the one between the afferent neuron and the efferent neuron. The withdrawal reflex and all other reflexes are **polysynaptic** (many synapses), because interneurons are interposed in the reflex pathway and, therefore, a number of synapses are involved.

Whenever a whole muscle is passively stretched, its muscle spindle intrafusal fibres are likewise stretched, which increases the firing rate in the afferent nerve fibres whose sensory endings terminate on the stretched spindle fibres. The afferent neuron directly synapses on the alpha motor neuron that innervates the extrafusal fibres of the same muscle, resulting in contraction of that muscle.

This stretch reflex serves as a local negative-feedback mechanism to resist any passive changes in muscle length so that optimal resting length can be maintained.

The classic example of the stretch reflex is the **patellar tendon (knee-jerk) reflex** (Figure 3-14). The extensor muscle of the knee is the *quadriceps femoris*, which forms the anterior (front) portion of the thigh and is attached just below the knee to the tibia (shinbone) by the *patellar tendon*. Tapping this tendon with a rubber mallet passively stretches the quadriceps muscle, activating its spindle receptors. The resulting stretch reflex brings about contraction of this extensor muscle, causing the knee to extend and raise the foreleg in the well-known knee-jerk fashion.

This test is routinely done as a preliminary assessment of nervous system function. A normal knee jerk indicates that a number of neural and muscular components—muscle spindle, afferent input, motor neurons, efferent output, neuromuscular junctions, and the muscles themselves—are functioning normally. It also indicates an appropriate balance of excitatory and inhibitory input to the motor neurons from higher brain levels. Muscle jerks may be absent or depressed with loss of higher-level excitatory inputs, or may be greatly exaggerated with loss of inhibitory input to the motor neurons from higher brain levels.

The primary purpose of the stretch reflex is to resist the tendency for the passive stretch of extensor muscles by gravitational forces when a person is standing upright. Whenever the knee joint

➤ **FIGURE 3-14 Patellar tendon reflex (a stretch reflex).** Tapping the patellar tendon with a rubber mallet stretches the muscle spindles in the quadriceps femoris muscle. The resultant monosynaptic stretch reflex results in contraction of this extensor muscle, causing the characteristic knee-jerk response.

tends to buckle because of gravity, the quadriceps muscle is stretched. The resulting enhanced contraction of this extensor muscle brought about by the stretch reflex quickly straightens out the knee, holding the limb extended so that the person remains standing.

WITHDRAWAL REFLEX

A basic **spinal reflex** (escape reflex) is one integrated by the spinal cord; that is, all components necessary for linking afferent input to efferent response are present within the spinal cord. The **withdrawal reflex** can serve to illustrate a basic spinal reflex (Figure 3-15). When a person touches a hot stove (or receives a painful stimulus), a withdrawal reflex is initiated to pull the hand away from the stove (to withdraw from the pain). The skin has different receptors for warmth, cold, light touch, pressure, and pain. Even though all information is sent to the CNS by way of action potentials, the CNS can distinguish between various stimuli because different receptors, and, consequently, different afferent pathways are activated by different stimuli. When a receptor is stimulated enough to reach threshold, an action potential is generated in the afferent sensory neuron. The stronger the stimulus, the greater the frequency of action potentials generated and propagated to the CNS. Once the afferent neuron enters the spinal cord, it diverges to synapse with the following different interneurons (the numbers correspond to those in Figure 3-15, step 3).

- (3a) An excited afferent neuron stimulates excitatory interneurons that in turn stimulate the efferent motor neurons supplying the biceps, the muscle in the arm that flexes (bends) the elbow joint. By concentrically contracting (shortening muscle fibres, p. 303), the biceps pulls the hand away from the hot stove.

- (3b) The afferent neuron also stimulates inhibitory interneurons that in turn inhibit the efferent neurons supplying the triceps to prevent it from contracting. The triceps is the muscle in the arm that extends (straightens out) the elbow joint. When the biceps is contracting to flex the elbow, it would be counterproductive for the triceps to be contracting concentrically. Thus, the triceps muscle relaxes (lengthens), allowing for a smooth, controlled motion. Therefore, built into the withdrawal reflex is inhibition of the muscle that antagonizes (opposes) the desired response. This type of neuronal connection involving stimulation of the nerve supply to one muscle and simultaneous inhibition of the nerves to its antagonistic muscle is known as **reciprocal innervation**.

- (3c) The afferent neuron stimulates still other interneurons that carry the signal up the spinal cord to the brain via an ascending pathway. Only when the impulse reaches the sensory area of the cortex is the person aware of the pain, its location, and the type of stimulus. As well, when the impulse reaches the brain, the information can be stored as memory, and the person can start thinking about the situation—how it happened, what to do about it, and so on. All this activity at the conscious level is above and beyond the basic reflex.

As is characteristic of all spinal reflexes, the brain can modify the withdrawal reflex. Impulses may be sent down descending pathways to the efferent motor neurons supplying the involved muscles to override the input from the receptors, actually preventing the biceps from contracting in spite of the painful stimulus. When your finger is pricked to obtain a blood sample, pain receptors are

1 Painful heat stimulus activates thermal pain receptor in finger.

2 Action potentials are generated in afferent pathway, which propagates impulses to the spinal cord.

3 Spinal cord serves as the integrating centre. Here afferent neuron stimulates **3a** excitatory interneurons, which stimulate motor neurons to biceps; **3b** inhibitory interneurons, which inhibit motor neurons to triceps; **3c** interneurons that are part of ascending pathway to brain.

4 One efferent pathway stimulates biceps to contract. Other efferent pathway leads to relaxation of triceps by preventing counterproductive excitation and contraction of this antagonistic muscle.

5 The biceps and triceps are effectors. Resultant flexion of elbow joint pulls hand away from painful stimulus. This response completes the withdrawal reflex.

6 Events that occur in brain on arrival of signal via ascending pathway, such as awareness of pain, memory storage, and so on, are above and beyond reflex arc.

FIGURE 3-15 The withdrawal reflex

stimulated, initiating the withdrawal reflex. Knowing that you must be brave and not pull your hand away, you can consciously override the reflex by sending IPSPs via descending pathways to the motor neurons supplying the biceps and EPSPs to those supplying the triceps. The activity in these efferent neurons depends on the sum of activity of all their synaptic inputs. Because the neurons supplying the biceps are now receiving more IPSPs from the brain (voluntary) than EPSPs from the afferent pain pathway (reflex), these neurons are inhibited and do not reach threshold. Therefore, the biceps is not stimulated to contract and withdraw the hand. Simultaneously, the neurons to the triceps are receiving more EPSPs from the brain than IPSPs via the reflex arc, so they reach threshold, fire, and consequently stimulate the triceps to contract. Thus, the arm is kept extended despite the painful stimulus. In this way, the withdrawal reflex has been voluntarily overridden.

THE BABINSKI ANKLE JERK REFLEX

Babinski reflex occurs when the big toe dorsiflexes (straightens) and the other toes fan outward after the lateral portion of the sole of the foot has been stimulated by a sweeping pressure (Figure 3-16). Babinski reflex is an infantile reflex, which is

normal up to two years of age. It disappears as the child ages and the nervous system develops, being replaced with a plantarflexion (bending) response. The presence of the Babinski reflex after age two is a sign of neurological issues associated with the CNS, and more specifically the corticospinal tract. As the corticospinal tract runs down both sides of the spinal cord, Babinski reflex can occur on one or both sides of the body. An abnormal Babinski reflex can be temporary or permanent. Some commonly associated diseases are amyotrophic lateral sclerosis, head injury, meningitis, multiple sclerosis, spinal cord injury, stroke, tuberculosis, and rabies.

OTHER REFLEX ACTIVITY

Spinal reflex action is not necessarily limited to motor responses on the side of the body to which the stimulus is applied. Assume that a person steps on a tack instead of burning a finger. A reflex arc is initiated to withdraw the injured foot from the painful stimulus, while the opposite leg simultaneously prepares to suddenly bear all the weight so that the person does not lose balance or fall (Figure 3-17). Unimpeded bending of the injured extremity's knee is accomplished by concurrent

► **FIGURE 3-16 Babinski reflex.** (a) The stimulation pattern on the sole of the foot. (b) A negative Babinski test. (c) A positive Babinski test

reflex stimulation of the muscles that flex the knee and inhibition of the muscles that extend the knee. This response is a typical withdrawal reflex. At the same time, unimpeded extension of the opposite limb's knee is accomplished by activation of pathways that cross over to the opposite side of the spinal cord to stimulate this knee's extensors and inhibit its flexors. This **crossed extensor reflex** ensures that the opposite limb will be in a position to bear the weight of the body as the injured limb is withdrawn from the stimulus.

Besides protective reflexes (such as the withdrawal reflex) and simple postural reflexes (such as the crossed extensor reflex), basic spinal reflexes mediate the emptying of pelvic organs (e.g., urination, defecation, and expulsion of semen). All spinal reflexes can be voluntarily overridden at least temporarily by higher brain centres.

Not all reflex activity involves a clear-cut reflex arc, although the basic principles of a reflex (i.e., an automatic response to a detectable change) are still present. Pathways for unconscious responsiveness digress from the typical reflex arc in two general ways:

1. *Responses mediated at least in part by hormones.* A particular reflex may be mediated solely by either neurons or hormones or may involve a pathway using both.

2. *Local responses that do not involve either nerves or hormones.* For example, the blood vessels in an exercising muscle dilate because of local metabolic changes, thereby increasing blood flow to match the active muscle's metabolic needs.

Check Your Understanding 3.3

1. Draw a cross section of a spinal cord and a pair of spinal nerves, showing the location of an afferent neuron, efferent neuron, and interneuron. Label the grey matter, white matter, dorsal root, ventral root, and spinal nerve.
2. Distinguish among a *tract*, *ganglion*, *nucleus*, *centre*, and *nerve*.

3.5 Brain Stem

The **brain stem** is inferior to (beneath) the occipital lobe and anterior (in front) of the cerebellum. It is an adjoining structure continuous with the spinal cord. The brain stem, consists of the *pons*, *medulla oblongata*, and *midbrain*. It has five functions, which will be discussed shortly (see Figure 3-21b).

© 2016 Cengage

► **FIGURE 3-17 The crossed extensor reflex coupled with the withdrawal reflex.** The withdrawal reflex, which causes flexion of the injured extremity to withdraw from a painful stimulus. The crossed extensor reflex, which extends the opposite limb to support the full weight of the body

A vital link

All incoming and outgoing fibres traversing between the periphery and higher brain centres must pass through the brain stem. Incoming fibres relay sensory information to the brain, and outgoing fibres carry command signals from the brain for efferent output. A few fibres merely pass through, but most synapse within the brain stem for important processing. Thus, the brain stem is a critical connecting link between the rest of the brain and the spinal cord.

The functions of the brain stem include the following:

1. The majority of the 12 pairs of **cranial nerves** arise from the brain stem (► Figure 3-18). With one major exception, these nerves supply structures in the head and neck with both sensory and motor fibres. They are important in sight, hearing, taste, smell, sensation of the face and scalp, eye movement, chewing, swallowing, facial expressions, and salivation. The major exception is cranial nerve X, the **vagus nerve**. Instead of innervating regions in the head, most branches of the vagus nerve supply organs in the thoracic and abdominal cavities. The vagus is the major nerve of the parasympathetic nervous system.
2. Within the brain stem are neuronal clusters, called centres, that control heart and blood vessel function, respiration, and many digestive activities.
3. The brain stem plays a role in regulating muscle reflexes involved in equilibrium and posture.
4. A widespread network of interconnected neurons, called the **reticular formation**, runs throughout the entire brain stem and superiorly into the thalamus. This network receives and integrates all incoming sensory synaptic input. Ascending fibres originating in the reticular

FIGURE 3-18 Cranial nerves. Inferior (underside) view of the brain, showing the attachments of the 12 pairs of cranial nerves to the brain and many of the structures innervated by those nerves

formation carry signals upward to arouse and activate the cerebral cortex (► Figure 3-19). These fibres compose the **reticular activating system (RAS)**, which controls the overall degree of cortical alertness and is important in the ability to direct attention. In turn, fibres descending from the cortex, especially its motor areas, can activate the RAS.

5. The centres of the brain that govern sleep traditionally have been considered to be housed within the brain stem, although recent evidence suggests that the centre that promotes slow-wave sleep lies in the hypothalamus (see Section 3.12).

3.6 | Thalamus and Hypothalamus

Deep within the brain near the basal ganglia is the **diencephalon**, a midline structure that forms the walls of the third ventricular cavity, one of the spaces through which CSF flows. The diencephalon consists of two main parts, the *thalamus* and the *hypothalamus* (► Figure 3-20; see also Figure 3-21b).

The thalamus

The **thalamus** serves as a “relay station” and synaptic integrating centre for preliminary processing of all sensory input on its way to the cortex. It screens out insignificant signals and routes the important sensory impulses to appropriate areas of the somatosensory cortex, as well as to other regions of the brain. Along with the brain stem and cortical association areas, the thalamus is important in the ability to direct attention to stimuli

of interest. For example, parents can sleep soundly through the noise of outdoor traffic but become instantly aware of their baby’s slightest whimper. The thalamus is also capable of crude awareness of various types of sensation but cannot distinguish their location or intensity. Some degree of consciousness resides

► **FIGURE 3-19 The reticular activating system.** The reticular formation, a widespread network of neurons within the brain stem (in red), receives and integrates all synaptic input. The reticular activating system, which promotes cortical alertness and helps direct attention toward specific events, consists of ascending fibres (in blue) that originate in the reticular formation and carry signals upward to arouse and activate the cerebral cortex.

► **FIGURE 3-20 Location of the thalamus, hypothalamus, and cerebellum in sagittal section**

here as well. As described in Section 3.5, the thalamus also plays an important role in motor control by positively reinforcing voluntary motor behaviour initiated by the cortex.

The hypothalamus

The **hypothalamus** is a collection of specific nuclei and associated fibres that lie inferior to (beneath) the thalamus. It is an integrating centre for homeostatic functions and is an important link between the autonomic nervous system and the endocrine system. Specifically, the hypothalamus (1) controls body temperature; (2) controls thirst and urine output; (3) controls food intake; (4) controls anterior pituitary hormone secretion; (5) produces posterior pituitary hormones; (6) controls uterine contractions and milk ejection; (7) serves as a major autonomic nervous system coordinating centre, which in turn affects all smooth muscle, cardiac muscle, and exocrine glands; (8) plays a role in emotional and behavioural patterns; and (9) participates in the sleep-wake cycle.

The hypothalamus is the brain area most involved in directly regulating the internal environment. For example, when the body is cold, the hypothalamus initiates internal responses to increase heat production (such as shivering) and to decrease heat loss (such as constricting blood vessels in the skin to reduce the flow of warm blood to the body surface, where heat could be lost to the external

environment). Other areas of the brain, such as the cerebral cortex, act more indirectly to regulate the internal environment. For example, a person who feels cold is motivated to voluntarily put on warmer clothing, close the window, turn up the thermostat, and so on. Even these voluntary behavioural activities are strongly influenced by the hypothalamus, which, as a part of the limbic system, functions together with the cortex in controlling emotions and motivated behaviour. We now turn our attention to the cerebral cortex.

Check Your Understanding 3.4

1. Describe how the thalamus serves as a sensory relay station.
2. Name the brain area most involved directly in regulating homeostatic functions.

3.7 | Cerebral Cortex

The cerebrum, by far the largest portion of the human brain, is divided into two halves, the right and left **cerebral hemispheres** (Figure 3-21a). They are connected to each other by the **corpus callosum**, a thick band consisting of an estimated 300 million neuronal axons travelling between the two hemispheres

3

FIGURE 3-21 Brain of human cadaver. (a) Dorsal view looking down on the top of the brain. Note that the deep longitudinal fissure divides the cerebrum into the right and left cerebral hemispheres. (b) Sagittal view of the right half of the brain. All major brain regions are visible from this midline interior view. The corpus callosum serves as a neural bridge between the two cerebral hemispheres.

Strokes: A Deadly Domino Effect

3

THE MOST COMMON CAUSE OF BRAIN DAMAGE is a **cerebrovascular accident (CVA)**, or stroke. When a brain (cerebral) blood vessel is blocked by a clot or ruptures, the brain tissue supplied by that vessel loses its vital oxygen and glucose supply. The result is damage and usually death of the deprived tissue. New findings show that neural damage (and the subsequent loss of neural function) extends well beyond the blood-deprived area as a result of a neurotoxic effect that leads to the death of additional nearby cells. Whereas the initial blood-deprived cells die by *necrosis* (unintentional cell death), the doomed neighbours undergo *apoptosis* (deliberate cell suicide). The initial oxygen-starved cells release excessive amounts of glutamate, a common excitatory neurotransmitter. Glutamate or other neurotransmitters are normally released in small amounts from neurons as a means of chemical communication

between brain cells. The excitatory overdose of glutamate from the damaged brain cells binds with and overexcites surrounding neurons. Specifically, glutamate binds with excitatory receptors known as NMDA receptors, which function as calcium K^+ channels. As a result of toxic activation of these receptor channels, they remain open for too long, permitting too much K^+ to rush into the affected neighbouring neurons. This elevated intracellular K^+ triggers these cells to self-destruct. During this process, **free radicals** are produced. These highly reactive, electron-deficient particles cause further cell damage by snatching electrons from other molecules. Adding to the injury, researchers speculate that the K^+ apoptotic signal may spread from the dying cells to abutting healthy cells through gap junctions—the cell-to-cell conduits that allow K^+ and other small ions to diffuse freely between cells. This action kills even more neuronal victims.

(Figure 3-21b; see also ▶ Figure 3-15). The corpus callosum is the body's "information superhighway." The two hemispheres communicate and cooperate with each other by means of constant information exchange through this neural connection.

The cerebral cortex: Grey matter and white matter

Each hemisphere is composed of a thin outer shell of *grey matter*, the **cerebral cortex**, covering a thick central core of *white matter* (see ▶ Figure 3-28). Another region of grey matter, the basal ganglia, is located deep within the white matter. Throughout the entire CNS, grey matter consists predominantly of densely packaged neuronal cell bodies and their dendrites as well as most glial cells. Bundles or tracts of myelinated nerve fibres (axons) constitute the white matter; its white appearance is due to the lipid composition of the myelin. The grey matter can be viewed as the computers of the CNS and the white matter as the wires that connect the computers to one another. Integration of neural input and initiation of neural output take place at synapses within the grey matter. The fibre tracts in the white matter transmit signals from one part of the cerebral cortex to another, or between the cortex and other regions of the CNS. Such communication between different areas of the cortex and elsewhere facilitates integration of their activity, which is essential for even a simple task, such as picking a flower. Vision of the flower is received by one area of the cortex, reception of its fragrance takes place in another area, and movement is initiated by still another area. More subtle neuronal responses, such as appreciation of the flower's beauty and the urge to pick it, are poorly understood but undoubtedly extensively involve interconnecting fibres between different cortical regions.

Layers and columns in the cerebral cortex

The cerebral cortex is organized into six well-defined layers based on varying distributions of several distinctive cell types. These layers are organized into functional vertical columns that extend perpendicularly about 2 mm from the cortical surface down through the thickness of the cortex to the underlying white matter. The neurons within a given column function as a team, with each cell being involved in different aspects of the same specific activity: for example, perceptual processing of the same stimulus from the same location.

The functional differences between various areas of the cortex result from different layering patterns within the columns and from different input–output connections, not from the presence of unique cell types or different neuronal mechanisms. For example, those regions of the cortex responsible for perception of senses have an expanded layer, a layer rich in **stellate cells**, which are responsible for initial processing of sensory input to the cortex. In contrast, cortical areas that control output to skeletal muscles have a thickened layer, which contains an abundance of large **pyramidal cells**. These cells send fibres down the spinal cord from the cortex to terminate on efferent motor neurons that innervate skeletal muscles.

Lobes in the cerebral cortex

We now consider the locations of the major functional areas of the cerebral cortex. Throughout this discussion, keep in mind that even though a discrete activity is ultimately attributed to a particular region of the brain, no part of the brain functions in isolation. Each part depends on a complex interplay among

Thus, the majority of neurons that die following a stroke are originally unharmed cells that commit suicide in response to the chain of reactions unleashed by the toxic release of glutamate from the initial site of oxygen deprivation.

Until the last decade, physicians could do nothing to halt the inevitable neuronal loss following a stroke, leaving patients with an unpredictable mix of neural deficits. Treatment was limited to rehabilitative therapy after the damage was already complete. In recent years, armed with new knowledge about the underlying factors in stroke-related neuronal death, the medical community has been seeking ways to halt the cell-killing domino effect. The goal, of course, is to limit the extent of neuronal damage and thus minimize, or even prevent, clinical symptoms such as paralysis. In the early 1990s doctors started administering clot-dissolving drugs within the

first three hours after the onset of a stroke to restore blood flow through blocked cerebral vessels. Clot busters were the first drugs used to treat strokes, but they are only the beginning of new stroke therapies. Other methods are currently under investigation to prevent adjacent nerve cells from succumbing to the neurotoxic release of glutamate. These include (1) blocking the NMDA receptors that initiate the neuronal death-wielding chain of events in response to glutamate, (2) halting the apoptosis pathway that results in self-execution, and (3) blocking the gap junctions that permit the K^+ death messenger to spread to adjacent cells. These tactics hold much promise for treating strokes, which are the most prevalent cause of adult disability and the third leading cause of death in Canada. However, to date no new neuroprotective drugs have been found that do not cause serious side effects.

numerous other regions for both incoming and outgoing messages.

The anatomic landmarks used in cortical mapping are certain deep folds that divide each half of the cortex into four major lobes: the *occipital*, *temporal*, *parietal*, and *frontal lobes* (Figure 3-22). To accompany the following discussion of the major activities attributed to various regions of these lobes, study the basic functional map of the cortex in Figure 3-23a.

The **occipital lobes**, located posteriorly (at the back of the head), carry out the initial processing of visual input. Sound sensation is initially received by the **temporal lobes**, located laterally (on the sides of the head) (Figures 3-23a and 3-23b). You will learn more about the functions of these regions in Chapter 4 when we discuss vision and hearing.

The frontal lobes and parietal lobes, located on the top of the head, are separated by a deep infolding, the **central sulcus**, which runs roughly down the middle of the lateral surface of each hemisphere. The **parietal lobes** lie to the rear of the central sulcus on each side, and the **frontal lobes** lie in front of it. The frontal lobes are responsible for three main functions: (1) voluntary motor activity, (2) speaking ability, and (3) elaboration of thought. The parietal lobes are primarily responsible for receiving and processing sensory input.

The frontal lobes

The area in the rear (dorsal) portion of the frontal lobe, immediately anterior of the central sulcus and adjacent to the somato-sensory cortex, is the **primary motor cortex** (Figure 3-24a; also see Figure 3-23a). It works in coordination with the premotor cortex (a few millimetres anterior of the primary motor cortex) to plan and execute movements. The primary motor cortex contains large pyramidal cell neurons (Betz cells, located in the grey matter) with long axons that descend the spinal cord and synapse (neurotransmitter glutamate) with the alpha-motor neurons of skeletal muscles. The premotor cortex also works in concert with the basal ganglia to plan movements or actions, and then receives input from the cerebellum to refine these movements (Section 3.8).

► **FIGURE 3-22 Cortical lobes.** Each half of the cerebral cortex is divided into the occipital, temporal, parietal, and frontal lobes, as depicted in this schematic lateral view of the brain.

As in sensory processing, the motor cortex on each side of the brain primarily controls muscles on the opposite side of the body. Neuronal tracts originating in the motor cortex of the left hemisphere cross over before passing down the spinal

cord to terminate on efferent motor neurons that stimulate skeletal muscle contraction on the right side of the body (see Figure 3-11b). Some fibres cross over to the opposite (contralateral) side in the medulla oblongata, and then the axons travel down the spinal cord as the lateral corticospinal tract. Other fibres travel down separately in ventral corticospinal tract with most crossing over to the contralateral side in the spinal cord just before reaching their associated motor neurons. Accordingly, damage to the motor cortex on the left side of the brain produces paralysis on the right side of the body, and the converse is also true.

Clinical Connections

Given that the cerebral cortex is involved in many functions, including cognition, speech, vision, and motor control, it is no surprise that any lesions in this area due to multiple sclerosis could present in numerous ways. The majority of Jackie's symptoms could be the result of scarring in this region of the brain, but it is important to note that multiple sclerosis generally leads to multiple lesion formations throughout the entire CNS, which suggests that any body function could be affected at multiple levels.

Stimulation of different areas of the primary motor cortex brings about movement in different regions of the body. Like the sensory homunculus for the somatosensory cortex, the **motor homunculus**, which depicts the location and relative amount of motor cortex devoted to output to the muscles of each body part, is upside down and distorted (Figure 3-24b). The fingers, thumbs, and muscles important in speech, especially those of the lips and tongue, are grossly exaggerated, indicating the fine degree of motor control these body parts have. Compare this with how little brain tissue is devoted to the trunk, arms, and lower extremities, which are not capable of such complex movements. This illustrates that the extent of representation in the motor cortex is proportional to the precision and complexity of motor skills required of the respective part.

The somatotopic map of the primary motor cortex is relatively stable as it pertains to the major body divisions (e.g., arm, leg). However, beneath the surface each of these map subdivisions is a distinct neuronal network that is not as stable. The underlying network of the primary motor cortex is not simply a static setup of horizontal neuronal connections; change and/or reorganization is possible. Neuronal activation patterns viewed through neuroimaging have shown that the primary motor cortex is plastic following both traumatic injury and everyday experiences (e.g., learning new motor skills). These neurons demonstrate activity-dependent plasticity and modify in association with learning new skills. The reorganization is likely dependent on excitatory and inhibitory influences within the horizontal neural connections, changes at the synapse, and the release of neurotransmitters (e.g., GABA).

► **FIGURE 3-23** Somatotopic map of the primary motor cortex. (a) Top view of cerebral hemispheres. (b) Motor homunculus showing the distribution of motor output from the primary motor cortex to different parts of the body. The distorted graphic representation of the body parts indicates the relative proportion of the primary motor cortex devoted to controlling skeletal muscles in each area.

The parietal lobes

Sensations from the surface of the body, such as touch, pressure, heat, cold, and pain, are collectively known as **somaesthetic sensations** (*somaesthetic* means “body feelings”). The

(b)

► **FIGURE 3-24 Functional areas of the cerebral cortex.** (a) Various regions of the cerebral cortex are primarily responsible for various aspects of neural processing, as indicated in this schematic lateral view of the brain. (b) Different areas of the brain “light up” on positron-emission tomography (PET) scans as a person performs different tasks. PET scans detect the magnitude of blood flow in various regions of the brain. Because more blood flows into a particular region of the brain when it is more active, neuroscientists can use PET scans to “take pictures” of the brain at work on various tasks.

means by which afferent neurons detect and relay information to the CNS about these sensations will be covered in Chapter 4, where we explore the afferent division of the PNS in detail and compare the perceptual maps of stimuli that activate A-beta (touch), A-delta (fast, pain), and C fibres (slow, heat) on the skin's surface. Within the CNS, this information is *projected* (i.e., transmitted along specific neural pathways to higher brain levels) to the **somatosensory cortex**. The somatosensory cortex is located in the front (anterior) portion of each

parietal lobe immediately behind (posterior) the central sulcus (Figures 3-23a and 3-25a). It is the site for initial cortical processing and perception of somesthetic input as well as proprioceptive input. **Proprioception** is the awareness of body position.

Each region within the somatosensory cortex receives somesthetic and proprioceptive input from a specific area of the body. This distribution of cortical sensory processing is depicted in Figure 3-25b. The mapping of the somatosensory cortex using

electrical stimulation by Penfield and colleagues (in the 1950s and earlier) gave us two important findings. First, representations of the skin surface have a generally somatotopic organization; for example, the hand representation is next to the arm

representation. Second, the cortical representations of body parts are larger for those that have higher sensitivity and use. This orderly somatotopic representation is named the **sensory homunculus** (*homunculus* means “little man”). The body is represented upside down on the somatosensory cortex, and as mentioned, different parts of the body are not equally represented. The size of each body part in this homunculus indicates the relative proportion of the somatosensory cortex devoted to that area. The exaggerated size of the face, tongue, hands, and genitalia indicates the high degree of sensory perception and/or use (e.g., touch) associated with these body parts.

For the most part, the somatosensory cortex on each side of the brain receives sensory input from the opposite side of the body, because most of the ascending pathways carrying sensory information up the spinal cord cross over to the opposite side before eventually terminating in the cortex (see Figure 3-11a). Therefore, damage to the somatosensory cortex in the left hemisphere produces sensory deficits on the right side of the body, whereas sensory losses on the left side are associated with damage to the right half of the cortex.

Simple awareness of touch, pressure, temperature, or pain is detected by the thalamus, a lower level of the brain, but the somatosensory cortex goes beyond pure recognition of sensations to fuller sensory perception. The thalamus makes you aware that something hot versus something cold is touching your body, but it does not tell you where or of what intensity. The somatosensory cortex localizes the source of sensory input and perceives the level of intensity of the stimulus. It also is capable of spatial discrimination, as it can discern shapes of objects being held, subtle differences in similar objects, and changes in limb position.

The somatosensory cortex, in turn, projects this sensory input via white matter fibres to adjacent higher sensory areas for even further elaboration, analysis, and integration of sensory information. These higher areas are important in perceiving complex patterns of somatosensory stimulation—for example, simultaneous appreciation of the texture, firmness, temperature, shape, position, and location of an object you are holding.

Other brain regions and motor control

Even though signals from the primary motor cortex terminate on the efferent neurons that trigger voluntary skeletal muscle contraction, the motor cortex is not the only brain region involved in motor control. First, lower brain regions and the spinal cord control involuntary skeletal muscle activity, such as in maintaining posture. Some of these same regions also play an important role in monitoring and coordinating voluntary motor activity that the primary motor cortex has set in motion. Second, although fibres originating from the motor cortex can activate motor neurons to bring about muscle contraction, the motor cortex itself does not *initiate* voluntary movement. The motor cortex is activated by a widespread pattern of neuronal discharge, the **readiness potential**, which occurs about 750 milliseconds before specific electrical activity is detectable in the motor cortex. Three higher motor areas of the cortex are involved in this voluntary decision-making period. These higher areas, which all command the primary motor cortex, include the *supplementary motor*

► **FIGURE 3-25** Somatotopic map of the somatosensory cortex. (a) Top view of cerebral hemispheres. (b) Sensory homunculus showing the distribution of sensory input to the somatosensory cortex from different parts of the body. The distorted graphic representation of the body parts indicates the relative proportion of the somatosensory cortex devoted to reception of sensory input from each area.

area, the *premotor cortex*, and the *posterior parietal cortex* (see Figure 3-23a). Furthermore, a **subcortical region** of the brain, the *cerebellum*, plays an important role, specifically, by sending input to the motor areas of the cortex regarding the planning, initiating, and timing certain kinds of movement.

The three higher motor areas of the cortex and the cerebellum carry out different, related functions that are all important in programming and coordinating complex movements that involve simultaneous contraction of many muscles. Even though electrical stimulation of the primary motor cortex brings about contraction of particular muscles, no purposeful coordinated movement can be elicited—just as pulling on isolated strings of a puppet does not produce any meaningful movement. A puppet displays purposeful movements only when a skilled puppeteer manipulates the strings in a coordinated manner. In the same way, these four regions (and perhaps other areas as yet undetermined) develop a **motor program** for the specific voluntary task and then “pull the appropriate pattern of strings” in the primary motor cortex to bring about the sequenced contraction of appropriate muscles to accomplish the desired complex movement.

The **supplementary motor area** lies on the medial (inner) surface of each hemisphere anterior (in front) of the primary motor cortex. It plays a preparatory role in programming complex sequences of movement—for example, those requiring simultaneous use of both hands and feet. Stimulation of various regions of this motor area brings about complex patterns of movement. Lesions here do not result in paralysis, but they do interfere with performance of more complex, useful, integrated movements.

The **premotor cortex**, located on the lateral surface of each hemisphere in front of the primary motor cortex, is important in orienting the body and arms (trunk muscles) toward a specific target. To command the primary motor cortex to bring about the appropriate skeletal muscle contraction to accomplish the desired movement, the premotor cortex must be informed of the body’s momentary position in relation to the target. The premotor cortex is guided by sensory input processed by the **posterior parietal cortex**, a region that lies posterior (behind) to the primary somatosensory cortex. These two higher motor areas have many anatomic interconnections and are closely interrelated functionally. When either of these areas is damaged, the person cannot process complex sensory information to accomplish purposeful movement in a spatial context; for example, the person cannot successfully manipulate eating with utensils. However, these higher motor areas command the primary motor cortex and are important in preparing for execution of deliberate, meaningful movement. Researchers cannot say, however, that voluntary movement is actually initiated by these areas.

Think about the neural systems called into play, for example, during the simple act of picking up an apple to eat. Your memory tells you that the fruit is in a bowl on the kitchen counter. Sensory systems, coupled with your knowledge based on past experience, enable you to distinguish the apple from the other kinds of fruit in the bowl. On receiving this integrated sensory information, motor systems issue commands to the exact muscles of the body in the proper sequence to enable you to move to the fruit bowl and pick up the targeted apple. During execution of

this act, minor adjustments in the motor command are made as needed, based on continual updating provided by sensory input about the position of your body relative to the goal. Then there is the issue of motivation and behaviour. Why are you reaching for the apple in the first place? Is it because you are hungry (detected by a neural system in the hypothalamus) or because of a more complex behavioural scenario unrelated to a basic hunger drive, such as the fact that you started to think about food because you just saw someone on television eating? Why did you choose an apple rather than a banana when both are in the fruit bowl and you like the taste of both, and so on? Consequently, initiating and executing purposeful voluntary movement actually include a complex neuronal interplay involving output from the motor regions that is guided by integrated sensory information and ultimately depends on motivational systems and elaboration of thought. All this plays against a background of memory stores from which you can make meaningful decisions about desirable movements.

Somatotopic maps

Although the general organizational pattern of sensory and motor somatotopic (body representation) maps of the cortex is similar in all people, the precise distribution is unique for each individual. Just as each of us has two eyes, a nose, and a mouth, and yet no two faces have these features arranged in exactly the same way, so it is with brains. Furthermore, an individual’s somatotopic mapping is not “carved in stone” but is subject to constant subtle modifications based on use.

When Penfield and colleagues did the original research on somatotopic mapping, they did not explore the manner in which the map could be altered by time and experience. Since then, research has shown that the primary somatosensory representations are plastic—that is, capable of changing in response to central or peripheral adjustments and experiences. For example, after an injury, tactile reduction occurs, altering the somatosensory maps. In contrast, following an amputation there is geographical expansion of the representations of neighbouring areas into the somatosensory cortex previously represented by the amputated body part.

It is known that altering body position results in changes in the perceived sensation and localization of touch. Localization is believed to occur in two stages: (1) the somatotopic stage in which a stimulus (e.g., pain) location is identified relative to its position on the skin surface, and (2) it takes into account limb position in external space. Thus, we must also know the location of our body to effectively localize the tactile stimuli relative to our environment.

Consequently, mapping is governed by both genetic and developmental processes, but the individual cortical setup can be influenced by **use-dependent competition** for cortical space. Here is another example of the adaptation of somatosensory mapping: When monkeys were encouraged to use a specific finger (middle finger), instead of other fingers to press a bar to release food, only after thousands of bar presses was the “middle finger area” of the motor cortex greatly expanded, to the point of intruding upon space previously devoted to the other fingers.

Other regions of the brain besides the somatosensory cortex and motor cortex can also be modified by experience. We are now going to turn our attention to this plasticity of the brain.

Plasticity and neurogenesis of brain tissue

From the previous discussion, you can see that the brain displays a degree of **plasticity**—that is, an ability to change or be functionally remodelled in response to the demands placed on it. The ability of the brain to modify as needed is more pronounced in the early developmental years, but even adults retain some plasticity (e.g., sensory and motor mapping). When an area of the brain associated with a particular activity is destroyed, other areas of the brain may gradually assume some or all of the functions of the damaged region. Researchers are only beginning to unravel the underlying molecular mechanisms responsible for the brain's plasticity. Current evidence suggests that the formation of new neural pathways (not new neurons, but new connections between existing neurons) in response to changes in experience are mediated in part by alterations in dendritic shape resulting from modifications in certain cytoskeletal elements (p. 130). As its dendrites become more branched and elongated, a neuron becomes able to receive and integrate more signals from other neurons. In this way, the precise synaptic connections between neurons are not fixed but can be modified by experience. The gradual modification of each person's brain by a unique set of experiences provides a biological basis for individuality.

In contrast to the growth of new neuronal connections, recently, adult neurogenesis (the creation of new brain cells) has been proposed. New neurons integrate themselves into the brain, providing the potential for self-healing. Neurogenesis could lead to improved treatments for disorders or damaged tissue (e.g., traumatic brain injury), and to ways to help keep our mind sharp. For example, hippocampal neurogenesis was demonstrated in humans, which may be important for learning and memory. Support for adult neurogenesis and improved memory include new neurons to increase memory capacity, reduction of interference between memories, and addition of temporal information to the memories.

Electroencephalograms

Extracellular current flow arising from electrical activity within the cerebral cortex can be detected by placing recording electrodes on the scalp to produce a graphic record known as an **electroencephalogram (EEG)**. These “brain waves” for the most part are not due to action potentials but instead represent the momentary collective postsynaptic potential activity (i.e., EPSPs and IPSPs; p. 76) in the cell bodies and dendrites located in the cortical layers under the recording electrode.

Electrical activity can always be recorded from the living brain, even during sleep and unconscious states, but the waveforms vary, depending on the degree of activity of the cerebral cortex. Often the waveforms appear irregular, but sometimes distinct patterns in the wave's amplitude and frequency can be observed. A dramatic example of this is illustrated in Figure 3-26, in which the EEG waveform recorded over the occipital (visual) cortex changes markedly in response to simply opening and closing the eyes.

► **FIGURE 3-26** Replacement of an alpha rhythm on an EEG with a beta rhythm when the eyes are opened

The EEG has three major uses:

1. The EEG is often used as a *clinical tool in the diagnosis of cerebral dysfunction*. Diseased or damaged cortical tissue often gives rise to altered EEG patterns. One of the most common neurologic diseases accompanied by a distinctively abnormal EEG is **epilepsy**. Epileptic seizures occur when a large collection of neurons abnormally undergo synchronous action potentials that produce stereotypical, involuntary spasms and alterations in behaviour. Different underlying problems, including genetic defects and traumatic brain injuries, can lead to the neuronal hyperexcitability that characterizes epilepsy. Typically, there is too little inhibitory compared with excitatory activity, as with compromised functioning of the inhibitory neurotransmitter GABA or prolonged action of the excitatory neurotransmitter glutamate. The seizures may be partial or generalized, depending on the location and extent of the abnormal neuronal discharge. Each type of seizure displays different EEG features.
2. The EEG finds further use in the *legal determination of brain death*. Even though a person may have stopped breathing and the heart may have stopped pumping blood, it is often possible to restore and maintain respiratory and circulatory activity if resuscitative measures are instituted soon enough. Yet because the brain is susceptible to oxygen deprivation, irreversible brain damage may have already occurred before lung and heart function have been re-established, resulting in the paradoxical situation of a dead brain in a living body. The determination of whether a comatose patient being maintained by artificial respiration and other supportive measures is alive or dead has important medical, legal, and social implications. The need for viable organs for modern transplant surgery has made the timeliness of such life/death determinations of utmost importance. Physicians, lawyers, and the Canadian public in general have accepted the notion of brain death—that is, a brain that is not functioning and has no possibility of recovery—as the determinant of death under such circumstances. Brain-dead people make good organ donors because the organs are still being supplied by circulating blood and thus are in better condition than those obtained from a person whose heart has stopped beating. The most widely accepted indication of brain death is

electrocerebral silence—an essentially flat EEG. This must be coupled with other stringent criteria, such as absence of eye reflexes, to guard against a false terminal diagnosis in individuals with a flat EEG that is due to causes that can be reversed, as in certain kinds of drug intoxication.

3. The EEG is also used to *distinguish various stages of sleep*, as described in Section 3.12.

Neurons

Most information about the electrical activity of the brain has been gleaned not from EEG studies but from direct recordings of individual neurons in experimental animals engaged in various activities. Following surgical implantation of an extremely thin recording microelectrode into a single neuron within a specific region of the cerebral cortex, scientists have been able to observe changes in the electrical activity of the neuron as the animal engages in particular motor tasks or encounters various sensations. Investigators have concluded that neural information is coded by changes in action potential frequency in specific neurons—the greater the triggering event, the greater the firing rate of the neuron.

Even though this finding is important, single-neuron recordings have not been able to identify concurrent changes in electrical activity in a group of neurons working together to accomplish a particular activity. As an analogy, consider if you tried to record a concert by using a single microphone that could pick up only the sounds produced by one musician. You would get a very limited impression of the performance by hearing only the changes in notes and tempo as played by this one individual. You would miss the richness of the melody and rhythm being performed in synchrony by the entire orchestra. Similarly, by recording from single neurons and detecting their changes in firing rates, scientists were unable to observe a parallel information mechanism that involves changes in the relative timing of action potential discharges among a functional group, or *assembly*, of neurons. By taking into account simultaneous recordings from multiple neurons, some researchers now suggest that interacting neurons may transiently fire together for fractions of a second. Many neuroscientists believe that the brain encodes information not just by changing the firing rates of individual neurons but also by changing the patterns of these brief neural synchronizations. That is, groups of neurons may communicate, or send messages about what is happening, by changing their pattern of synchronous firing.

Neurons within an assembly that fire together may be widely scattered, but integrated. For example, when you view a bouncing ball, different visual units initially process different aspects of this object—its shape, its colour, its movement, and so on. Somehow all these separate processing pathways must be integrated, or bound together, for you to see the bouncing ball as a whole unit without stopping to contemplate its many separate features. The solution to the mystery of how the brain accomplishes this task might lie in the synchronous firing of neurons in separate regions of the brain that are functionally linked by virtue of being responsive to different aspects of the same objects—such as the bouncing ball.

Check Your Understanding 3.5

1. Draw a lateral view of the left cerebral cortex, and then label the location of each of the following: frontal lobe, parietal lobe, occipital lobe, temporal lobe, primary motor cortex, somatosensory cortex, primary visual cortex, auditory cortex, and prefrontal association cortex.
2. Define *plasticity*.

3.8 | Cerebellum

The **cerebellum** means “little brain” in Latin. It is a baseball-sized region located inferiorly to the occipital lobe and posteriorly to the brain stem. The cerebellum is central to the integration of motor output and sensory perception. It is linked by neural pathways to the motor cortex, which sends information to the skeletal muscles, causing movement, and to the spinocerebellar tract, which provides feedback on body position (proprioception) (see Figures 3-21b and 3-20).

Balance and planning

More individual neurons are found in the cerebellum than in the rest of the brain, indicative of the importance of this structure. The cerebellum consists of three functionally distinct parts, each with different roles concerned primarily with subconscious control of motor activity (► Figure 3-27). Specifically, the different parts of the cerebellum perform the following functions:

1. The **vestibulocerebellum** is important for maintaining balance and controls eye movements.
2. The **spinocerebellum** enhances muscle tone and coordinates skilled, voluntary movements. This brain region is especially important in ensuring the accurate timing of various muscle contractions to coordinate movements involving multiple joints. For example, the movements of your shoulder, elbow, and wrist joints must be synchronized even during the simple act of reaching for a pencil. When cortical motor areas send messages to muscles for executing a particular movement, the spinocerebellum is informed of the intended motor command. This region also receives input from peripheral receptors that inform it about the body movements and positions that are actually taking place. The spinocerebellum essentially acts as middle management, comparing the intentions or orders of the executive management (motor cortex) with the performance of the lower levels of the organization (muscles) and then correcting any errors or deviations from the intended outcomes (movement). The spinocerebellum even seems able to predict the position of a body part in the next fraction of a second during a complex movement and to make adjustments accordingly. If you are reaching for a pencil, for example, this region “puts on the brakes” soon enough to stop the forward movement of your hand

► **FIGURE 3-27 Cerebellum.** (a) Gross structure of the cerebellum. (b) Unfolded cerebellum, revealing its three functionally distinct parts. (c) Internal structure of the cerebellum

at the intended location rather than letting you overshoot your target. These ongoing adjustments, which ensure smooth, precise, directed movement, are especially important for rapidly changing (phasic) activities, such as typing, playing the piano, or running.

3. The **cerebrocerebellum** plays a role in planning and initiating voluntary activity by providing input to the cortical motor areas. This is also the cerebellar region that stores procedural memories.

Recent discoveries suggest that in addition to these well-established functions, the cerebellum has even broader responsibilities, such as perhaps coordinating the brain's acquisition of sensory input. Researchers are currently trying to make sense of new and surprising findings that do not fit with the cerebellum's traditional roles in motor control.

The following symptoms of cerebellar disease can be referred to a loss of the cerebellum's established motor functions: poor balance, nystagmus (rhythmic, oscillating eye movements),

reduced muscle tone but no paralysis, inability to perform rapid movements smoothly, and inability to stop and start skeletal muscle action quickly. The latter gives rise to an *intention tremor* characterized by oscillating to-and-fro movements of a limb as it approaches its intended destination. In trying to pick up a pencil, a person with cerebellar damage may overshoot the pencil and then rebound excessively, repeating this to-and-fro process until successful. No tremor is observed except in performing intentional activity, in contrast to the resting tremor associated with disease of the basal ganglia, most notably Parkinson's disease.

The cerebellum and basal ganglia both monitor and adjust motor activity commanded from the motor cortex, and, like the basal ganglia, the cerebellum does not directly influence the efferent motor neurons. Although they perform different roles (e.g., the cerebellum enhances muscle tone, whereas the basal ganglia inhibit it), both function indirectly by modifying the output of major motor systems in the brain. The motor command for a particular voluntary activity arises from the motor cortex, but the actual execution of that activity is coordinated

subconsciously by these subcortical regions. To illustrate, you can voluntarily decide to get up and walk, but you do not have to consciously think about the specific sequence of movements needed to accomplish this intentional act. Accordingly, much voluntary activity is actually involuntarily regulated. You will learn more about motor control when we discuss muscle physiology in Chapter 7.

3.9 | Basal Ganglia

The **basal ganglia** consist of several masses of grey matter located deep within the cerebral white matter (▶ Figure 3-28) and are associated with a variety of functions, including motor control, cognition, emotions, and learning.

▶ **FIGURE 3-28 Frontal section of the brain.** (a) Schematic frontal section of the brain. The cerebral cortex, an outer shell of grey matter, surrounds an inner core of white matter. Deep within the cerebral white matter are several masses of grey matter, the basal ganglia. The ventricles are cavities in the brain through which the cerebrospinal fluid flows. The thalamus forms the walls of the third ventricle. (b) Photograph of a frontal section of the brain of a cadaver

The basal ganglia play a complex role in controlling movement, in addition to having nonmotor functions that are less understood. More specifically, the basal ganglia are important in (1) inhibiting muscle tone throughout the body (proper muscle tone is normally maintained by a balance of excitatory and inhibitory inputs to the neurons that innervate skeletal muscles); (2) selecting and maintaining purposeful motor activity while suppressing useless or unwanted patterns of movement; and (3) helping monitor and coordinate slow, sustained contractions, especially those related to posture and support. The basal ganglia do not directly influence the efferent motor neurons that bring about muscle contraction but do modify ongoing activity in motor pathways.

To accomplish these complex integrative roles, the basal ganglia receive and send out much information, as is indicated by the tremendous number of fibres linking them to other regions of the brain—for example, the strategic interconnections that form a complex feedback loop linking the cerebral cortex (especially its motor regions), the basal ganglia, and the thalamus. The thalamus positively reinforces voluntary motor behaviour initiated by the cortex, whereas the basal ganglia modulate this activity by exerting an inhibitory effect on the thalamus to eliminate antagonistic or unnecessary movements. The basal ganglia also exert an inhibitory effect on motor activity by acting through neurons in the brain stem.

The importance of the basal ganglia in motor control is evident in diseases involving this region, the most common of which is *Parkinson's disease (PD)*. This condition is associated with a deficiency of dopamine, an important neurotransmitter in the basal ganglia (see *Integration of Human Physiology: Movement and Parkinson's Disease*, p. 339). Because the basal ganglia lack enough dopamine to exert their normal roles, three types of motor disturbances characterize PD: (1) increased muscle tone, or rigidity; (2) involuntary, useless, or unwanted movements, such as *resting tremors* (e.g., hands rhythmically shaking, making it difficult or impossible to hold a cup of coffee); and (3) slowness in initiating and carrying out different motor behaviours. People with PD find it difficult to stop ongoing activities. If sitting down, they tend to remain seated, and if they get up, they do so very slowly.

3.10 The Limbic System and Its Functional Relations with the Higher Cortex

The **limbic system** is not a separate structure but a ring of fore-brain structures that surround the brain stem and are interconnected by intricate neuron pathways (► Figure 3-29). It includes portions of each of the following: the lobes of the cerebral cortex (especially the limbic association cortex), the basal ganglia, the thalamus, and the hypothalamus. This complex interacting network is associated with emotions, basic survival and sociosexual behavioural patterns, motivation, and learning. Let's examine each of these brain functions further.

The limbic system and emotion

The concept of **emotion** encompasses subjective emotional feelings and moods (such as anger, fear, and happiness) plus the overt physical responses associated with these feelings. These responses include specific behavioural patterns (e.g., preparing for attack or defence when angered by an adversary) and observable emotional expressions (e.g., laughing, crying, or blushing). Evidence points to a central role for the limbic system in all aspects of emotion. Stimulating specific regions within the limbic system of humans during brain surgery produces various vague subjective sensations that the patient describes as joy, satisfaction, or pleasure in one region and discouragement, fear, or anxiety in another. For example, the **amygdala**, on the interior underside of the temporal lobe (Figure 3-29), is an especially important region for processing inputs that give rise to the sensation of fear. In humans and to an undetermined extent in other species, higher levels of the cortex are also crucial for conscious awareness of emotional feelings.

The control of basic behavioural patterns

Basic behavioural patterns controlled at least in part by the limbic system include those aimed at individual survival (attack, searching for food) and those directed toward perpetuating the species (sociosexual behaviours conducive to mating). In experimental animals, stimulating the limbic system brings about complex and even bizarre behaviours. For example, stimulation in one area can elicit responses of anger and rage in a normally docile animal, whereas stimulation in another area results in placidity and tameness, even in an otherwise vicious animal. Stimulation in yet another limbic area can induce sexual behaviours, such as copulatory movements.

► **FIGURE 3-29 Limbic system.** This partially transparent view of the brain reveals the structures composing the limbic system.

ROLE OF THE HYPOTHALAMUS IN BASIC BEHAVIOURAL PATTERNS

The relationships among the hypothalamus, limbic system, and higher cortical regions regarding emotions and behaviour are still not well understood. Apparently the extensive involvement of the hypothalamus in the limbic system governs the involuntary internal responses of various body systems in preparation for appropriate action to accompany a particular emotional state. For example, the hypothalamus controls the increase of heart rate and respiratory rate, elevation of blood pressure, and diversion of blood to skeletal muscles that occur in anticipation of attack or when angered. These preparatory changes in the internal state require no conscious control.

ROLE OF THE HIGHER CORTEX IN BASIC BEHAVIOURAL PATTERNS

In executing complex behavioural activities, such as attack, flight, or mating, the individual (animal or human) must interact with the external environment. Higher cortical mechanisms are called into play to connect the limbic system and hypothalamus with the outer world so that appropriate overt behaviours are manifested. At the simplest level, the cortex provides the neural mechanisms necessary for implementing the appropriate skeletal muscle activity required to approach or avoid an adversary, participate in sexual activity, or display emotional expression. For example, the stereotypical sequence of movement for the universal human emotional expression of smiling is apparently preprogrammed in the cortex and can be called forth by the limbic system. One can also voluntarily call forth the smile program, as when posing for a picture. Even individuals who are blind from birth have normal facial expressions; that is, they do not learn to smile by observation. Smiling means the same thing in every culture, despite widely differing environmental experiences. Such behavioural patterns shared by all members of a species are believed to be more abundant in lower animals.

Higher cortical levels also can reinforce, modify, or suppress basic behavioural responses so that actions can be guided by planning, strategy, and judgment based on an understanding of the situation. Even if you were angry at someone and your body were internally preparing for attack, you probably would judge that an attack would be inappropriate and could consciously suppress the external manifestation of this basic emotional behaviour. Thus, the higher levels of the cortex, particularly the prefrontal and limbic association areas, are important in conscious, learned control of innate behavioural patterns. Using fear as an example, exposure to an aversive experience calls two parallel tracks into play for processing this emotional stimulus: a fast track in which the lower-level amygdala plays a key role, and a slower track mediated primarily by the higher-level prefrontal cortex. The fast track permits a rapid, rather crude, instinctive response—a gut reaction—and is essential for the feeling of being afraid. The slower track involving the prefrontal cortex permits a more refined response to the aversive stimulus, based on a rational analysis of the current situation compared with stored past experiences. The prefrontal cortex formulates plans and guides behaviour, thereby suppressing amygdala-induced responses that may be inappropriate for the situation at hand.

REWARD AND PUNISHMENT CENTRES

An individual tends to reinforce behaviours that have proved gratifying and to suppress behaviours that have been associated with unpleasant experiences. Certain regions of the limbic system have been designated as **reward centres** and **punishment centres**, because stimulation in these respective areas gives rise to pleasant or unpleasant sensations. When a self-stimulating device is implanted in a reward centre, an experimental animal will self-deliver up to 5000 stimulations per hour and will even shun food when starving, in preference for the pleasure derived from self-stimulation. In contrast, when the device is implanted in a punishment centre, animals will avoid stimulation at all costs. Reward centres are found most abundantly in regions involved in mediating the highly motivated behavioural activities of eating, drinking, and sexual activity.

Motivated behaviours

Motivation is the ability to direct behaviour toward specific goals. Some goal-directed behaviours are aimed at satisfying specific identifiable physical needs related to homeostasis. **Homeostatic drives** represent the subjective urges associated with specific bodily needs that motivate appropriate behaviour to satisfy those needs. For example, the sensation of thirst accompanying a water deficit in the body drives an individual to drink to satisfy the homeostatic need for water. However, whether water, a soft drink, or another beverage is chosen as the thirst quencher is unrelated to homeostasis. Much human behaviour does not depend on purely homeostatic drives related to simple tissue deficits, such as thirst. Human behaviour is influenced by experience, learning, and habit, shaped in a complex framework of unique personal gratifications blended with cultural expectations. To what extent, if any, motivational drives unrelated to homeostasis, such as the drive to pursue a particular career or win a certain race, are involved with the reinforcing effects of the reward and punishment centres is unknown. Indeed, some individuals motivated toward a particular goal may even deliberately “punish” themselves in the short term to achieve their long-range gratification (e.g., the temporary pain of training in preparation for winning a competitive athletic event).

Neurotransmitters in pathways for emotions and behaviour

The underlying neurophysiological mechanisms responsible for the psychological observations of emotions and motivated behaviour largely remain a mystery, although the neurotransmitters *norepinephrine*, *dopamine*, and *serotonin* all have been implicated. Norepinephrine and dopamine, both chemically classified as *catecholamines*, are known transmitters in the regions that elicit the highest rates of self-stimulation in animals equipped with do-it-yourself devices. A number of **psychoactive drugs** affect moods in humans, and some of these drugs have also been shown to influence self-stimulation in experimental animals. For example, increased self-stimulation is observed after the administration of drugs that increase catecholamine synaptic activity, such as *amphetamine*, an “upper” drug.

Although most psychoactive drugs are used therapeutically to treat various mental disorders, others, unfortunately, are abused. Many abused drugs act by enhancing the effectiveness of dopamine in the pleasure pathways, initially giving rise to an intense sensation of pleasure. As you learned in Chapter 2, one example is cocaine, which blocks the reuptake of dopamine at synapses (p. 82).

Depression is among the mental disorders associated with defects in limbic system neurotransmitters. A functional deficiency of serotonin or norepinephrine or both is implicated in depression, a disorder characterized by a pervasive negative mood accompanied by a generalized loss of interests, an inability to experience pleasure, and suicidal tendencies. All effective antidepressant drugs increase the available concentration of these neurotransmitters in the CNS. *Prozac*, one of the most commonly prescribed drugs in Canadian psychiatry, is illustrative. It blocks the reuptake of released serotonin, thus prolonging serotonin activity at synapses. Serotonin and norepinephrine are synaptic messengers in the limbic regions of the brain involved in pleasure and motivation, suggesting that the pervasive sadness and lack of interest (no motivation) in depressed patients are related at least in part to disruption of these regions by deficiencies or decreased effectiveness of these neurotransmitters.

Researchers are optimistic that as understanding of the molecular mechanisms of mental disorders is expanded in the future, many psychiatric problems can be corrected or better managed through drug intervention, a hope of great medical significance.

2. Name the brain area most important in processing the sensation of fear.

3.11 | Learning, Memory, and Language

Learning

Learning is the acquisition of knowledge or skills as a consequence of experience, instruction, or both. It is widely believed that rewards and punishments are integral parts of many types of learning. If an animal is rewarded on responding in a particular way to a stimulus, the likelihood increases that the animal will respond in the same way again to the same stimulus as a consequence of this experience. Conversely, if a particular response is accompanied by punishment, the animal is less likely to repeat the same response to the same stimulus. When behavioural responses that give rise to pleasure are reinforced or those accompanied by punishment are avoided, learning has taken place. Housebreaking a puppy is an example. If the puppy is praised when it urinates outdoors but scolded when it wets the carpet, it soon learns the acceptable place to empty its bladder. In

this regard, learning involves a change in behaviour that occurs as a result of experiences. It is highly dependent on the organism's interaction with its environment. The only limits to the effects that environmental influences can have on learning are the biological constraints imposed by species-specific and individual genetic endowments.

Memory

Memory is the storage of acquired knowledge for later recall. Learning and memory form the basis by which individuals adapt their behaviour to their particular external circumstances. Without these mechanisms, it would be impossible for individuals to plan for successful interactions and to intentionally avoid predictably disagreeable circumstances.

The neural change responsible for retention or storage of knowledge is known as the **memory trace**. Generally, concepts—not verbatim information—are stored. As you read this page, you are storing the concept discussed, not the specific words. Later, when you retrieve the concept from memory, you will convert it into your own words. It is possible, however, to memorize bits of information word by word.

Storage of acquired information is accomplished in at least two stages: short-term memory and long-term memory (Table 3-3). **Short-term memory** lasts for seconds to hours, whereas **long-term memory** is retained for days to years. The process of transferring and fixing short-term memory traces into long-term memory stores is known as **consolidation**.

A recently developed concept is that of **working memory**, or what has been called “the erasable blackboard of the mind.” Working memory temporarily holds and interrelates various pieces of information relevant to a current mental task. Through your working memory, you briefly hold and process data for immediate use—both newly acquired information and related, previously stored knowledge that is transiently brought forth into working memory—so that you can evaluate the incoming data in context. This integrative function is crucial to your ability to reason, plan, and make judgments. By comparing and manipulating new and old information within your working memory, you can comprehend what you are reading, carry on a conversation, calculate a restaurant tip in your head, find your way home, and know that you should put on warm clothing if you see snow outside. In short, working memory enables people to string thoughts together in a logical sequence and plan for future action.

Although strong evidence is still lacking, new findings hint that once an established memory is actively recalled, it becomes labile (unstable or subject to change) and must be **reconsolidated** back into a restabilized, inactive state. According to this controversial proposal, new information may be incorporated into the old memory trace during reconsolidation.

COMPARISON OF SHORT-TERM AND LONG-TERM MEMORY

Newly acquired information is initially deposited in short-term memory, which has a limited capacity for storage. Information in short-term memory has one of two eventual fates. Either it is soon forgotten (e.g.,

■ TABLE 3-3 Comparison of Short-Term and Long-Term Memory

Characteristic	Short-Term Memory	Long-Term Memory
Time of storage after acquisition of new information	Immediate	Later; must be transferred from short-term to long-term memory through consolidation; enhanced by practice or recycling of information through short-term mode
Duration	Lasts for seconds to hours	Retained for days to years
Capacity of storage	Limited	Very large
Retrieval time (remembering)	Rapid retrieval	Slower retrieval, except for thoroughly ingrained memories, which are rapidly retrieved
Inability to retrieve (forgetting)	Permanently forgotten; memory fades quickly unless consolidated into long-term memory	Usually only transiently unable to access; relatively stable memory trace
Mechanism of storage	Involves transient modifications in functions of pre-existing synapses, such as altering amount of neurotransmitter released	Involves relatively permanent functional or structural changes between existing neurons, such as formation of new synapses; synthesis of new proteins plays a key role

© 2016 Cengage

3

forgetting a telephone number after you have looked it up and finished dialling), or it is transferred into the more permanent long-term memory mode through *active practice* or *rehearsal*. The recycling of newly acquired information through short-term memory increases the likelihood that the information will be consolidated into long-term memory. (Therefore, when you cram for an exam, your long-term retention of the information is poor!) This relationship can be likened to developing photographic film. The originally developed image (short-term memory) rapidly fades unless it is chemically fixed (consolidated) to provide a more enduring image (long-term memory). Sometimes only parts of memories are fixed, whereas others fade away. Information of interest or importance to the individual is more likely to be recycled and fixed in long-term stores, whereas less important information is quickly erased.

The storage capacity of the long-term memory bank is much larger than the capacity of short-term memory. Different informational aspects of long-term memory traces seem to be processed and codified, then stored with other memories of the same type; for example, visual memories are stored separately from auditory memories. This organization facilitates future searching of memory stores to retrieve desired information. For example, in remembering a woman you once met, you may use various recall cues from different storage pools, such as her name, her appearance, the fragrance she wore, an incisive point she made, or the song playing in the background.

Stored knowledge is of no use unless it can be retrieved and used to influence current or future behaviour. Because long-term memory stores are larger, it often takes longer to retrieve information from long-term memory than from short-term memory. *Remembering* is the process of retrieving specific information from memory stores; *forgetting* is the inability to retrieve stored

information. Information lost from short-term memory is permanently forgotten, but information in long-term storage is frequently forgotten only transiently. Often you are only temporarily unable to access the information—for example, not being able to remember an acquaintance's name, then having it suddenly occur to you later.

Some forms of long-term memory involving information or skills used on a daily basis are essentially never forgotten and are rapidly accessible, such as knowing your own name or being able to write. Even though long-term memories are relatively stable, stored information may be gradually lost or modified over time, unless it is thoroughly ingrained as a result of years of practice.

AMNESIA

Occasionally, individuals suffer from a lack of memory that involves whole portions of time rather than isolated bits of information. This condition, known as **amnesia**, occurs in two forms. The most common form, *retrograde* (going backward) *amnesia*, is the inability to recall recent past events. It usually follows a traumatic event that interferes with electrical activity of the brain, such as a concussion or stroke. If a person is knocked unconscious, the content of short-term memory is essentially erased, resulting in loss of memory about activities that occurred within about the last half hour before the event. Severe trauma may interfere with access to recently acquired information in long-term stores as well.

Anterograde (going forward) *amnesia*, conversely, is the inability to store memory long term for later retrieval. It is usually associated with lesions of the medial portions of the temporal lobes, which are generally considered critical regions for memory consolidation. People suffering from this condition may be able to recall things they learned before the onset of their

problem, but they cannot establish new permanent memories. New information is lost as quickly as it fades from short-term memory. In one case study, the person could not remember where the bathroom was in his new home but still had total recall of his old home.

Memory traces

What parts of the brain are responsible for memory? There is no single memory centre in the brain. Instead, the neurons involved in memory traces are widely distributed throughout the subcortical and cortical regions of the brain. The regions of the brain most extensively implicated in memory include the hippocampus and associated structures of the medial (inner) temporal lobes, the limbic system, the cerebellum, the prefrontal cortex, and other regions of the cerebral cortex.

3 THE HIPPOCAMPUS AND DECLARATIVE MEMORIES

The **hippocampus** is the elongated, medial portion of the temporal lobe that is part of the limbic system (see Figure 3-29). It plays a vital role in short-term memory involving the integration of various related stimuli and is also crucial for consolidation into long-term memory. The hippocampus is believed to store new long-term memories only temporarily and then transfer them to other cortical sites for more permanent storage. The sites for long-term storage of various types of memories are only beginning to be identified by neuroscientists.

The hippocampus and surrounding regions play an especially important role in **declarative memories**—the “what” memories of specific people, places, objects, facts, and events. This type of memory often results after only one experience and can be declared in a statement such as, “I saw the CN Tower last summer” or conjured up in a mental image. Declarative memories require conscious recall. The hippocampus and associated temporal/limbic structures are especially important in maintaining a durable record of the everyday episodic events in our lives.

People with hippocampal damage are profoundly forgetful of facts critical to daily functioning. Declarative memories typically are the first to be lost. Interestingly, extensive damage in the hippocampus region is evident during autopsy in patients with Alzheimer’s disease.

THE CEREBELLUM AND PROCEDURAL MEMORIES

In contrast to the role of the hippocampus and surrounding temporal/limbic regions in declarative memories, the cerebellum and relevant cortical regions play an essential role in **procedural memories**—the “how to” memories involving motor skills gained through repetitive training, such as memorizing a particular dance routine. The cortical areas important for a given procedural memory are the specific motor or sensory systems engaged in performing the routine. In contrast to declarative memories, which are consciously recollected from previous experiences, procedural memories can be brought forth without conscious effort. For example, during a competition, an ice skater typically performs best by “letting the body take over” the routine instead of thinking about exactly what needs to be done next.

The distinct localization in different parts of the brain of these two types of memory is apparent in people who have temporal/limbic lesions. They can perform a skill, such as playing a piano, but the next day they have no recollection that they did so.

THE PREFRONTAL CORTEX AND WORKING MEMORY

The major orchestrator of the complex reasoning skills associated with *working memory* is the prefrontal association cortex. The prefrontal cortex not only serves as a temporary on-line storage site for holding relevant data but also is largely responsible for the so-called executive functions involving manipulation and integration of information for planning, juggling competing priorities, problem solving, and organizing activities. The prefrontal cortex carries out these complex reasoning functions in cooperation with all the brain’s sensory regions, which are linked to the prefrontal cortex through neural connections. Researchers have identified different storage bins in the prefrontal cortex, depending on the nature of the current relevant data. For example, working memory involving spatial cues is in a prefrontal location distinct from working memory involving verbal cues or cues about an object’s appearance. A recent fascinating proposal suggests that level of intelligence may be determined by the capacity of a person’s working memory to temporarily hold and relate a variety of relevant data.

Short-term and long-term memory: Different molecular mechanisms

As well as the question of where memory is stored, there is the question of how it is stored. Despite a vast amount of psychological data, only a few tantalizing scraps of physiological evidence concerning the cellular basis of memory traces are available. Obviously, some change must take place within the neural circuitry of the brain to account for the altered behaviour that follows learning. A single memory does not reside in a single neuron but rather in changes in the pattern of signals transmitted across synapses within a vast neuronal network.

Different mechanisms are responsible for short-term and long-term memory. Short-term memory involves transient modifications in the function of pre-existing synapses, such as a temporary change in the amount of neurotransmitter released in response to stimulation or a temporary increased responsiveness of the postsynaptic cell to the neurotransmitter within affected nerve pathways. Long-term memory, in contrast, involves relatively permanent functional or structural changes between existing neurons in the brain. Let’s look at each of these types of memory in more detail.

Short-term memory

Experiments in the sea snail *Aplysia* have shown that two forms of short-term memory—habituation and sensitization—are due to modification of different channel proteins in presynaptic terminals of specific afferent neurons involved in the pathway that mediates the behaviour being modified. This modification, in turn, brings about changes in transmitter release. **Habituation**

is a decreased responsiveness to repetitive presentations of an indifferent stimulus—that is, one that is neither rewarding nor punishing. **Sensitization** is increased responsiveness to mild stimuli following a strong or noxious stimulus. *Aplysia* reflexly withdraws its gill when its siphon, a breathing organ at the top of its gill, is touched. Afferent neurons responding to touch of the siphon (presynaptic neurons) directly synapse on efferent motor neurons (postsynaptic neurons) controlling gill withdrawal. The snail becomes habituated when its siphon is repeatedly touched; that is, it learns to ignore the stimulus and no longer withdraws its gill in response. Sensitization, a more complex form of learning, takes place in *Aplysia* when it is given a hard bang on the siphon. Subsequently, the snail withdraws its gill more vigorously in response to even mild touch. Interestingly, these different forms of learning affect the same site—the synapse between a siphon afferent and a gill efferent—in opposite ways. Habituation depresses this synaptic activity, whereas sensitization enhances it (▶ Figure 3-30). These transient modifications persist for as long as the time course of the memory.

MECHANISM OF HABITUATION

In habituation, the closing of K^+ channels reduces K^+ entry into the presynaptic terminal, which leads to a decrease in neurotransmitter release. As a consequence, the postsynaptic potential is reduced compared with normal, resulting in a decrease or absence of the behavioural response controlled by the postsynaptic efferent neuron (gill withdrawal in *Aplysia*). Thus, the memory for habituation in *Aplysia* is stored in the form of modification of specific K^+ channels. With no further training, this reduced responsiveness lasts for several hours. A similar process is responsible for short-term habituation in other species studied. This suggests that K^+ channel modification is a general mechanism of habituation; however, in higher species the involvement of intervening interneurons makes the process somewhat more complicated. Habituation is probably the most common form of learning and is believed to be the first learning process to take place in human infants. By learning to ignore indifferent stimuli, the animal or person is free to attend to other more important stimuli.

MECHANISM OF SENSITIZATION

Sensitization in *Aplysia* also involves channel modification, but a different channel and mechanism are involved. In contrast to what happens in habituation, K^+ entry into the presynaptic terminal is enhanced in sensitization. The subsequent increase in neurotransmitter release produces a larger postsynaptic potential, resulting in a more vigorous gill-withdrawal response. Sensitization does not have a direct effect on presynaptic K^+ channels. Instead, it indirectly enhances K^+ entry via presynaptic facilitation (p. 81). The neurotransmitter serotonin is released from a facilitating interneuron that synapses on the presynaptic terminal to bring about increased release of presynaptic neurotransmitter in response to an action potential. It does so by triggering activation of a cyclic AMP (adenosine monophosphate) second messenger within the presynaptic terminal, which ultimately brings about an inhibition of K^+ channel function in the terminals. Cyclic AMP is a second messenger used in many

biological processes, and is derived from adenosine triphosphate (ATP) and used for intracellular signal transduction (see more information on cyclic AMP in Chapter 5, p. 217). This blockage prolongs the action potential in the presynaptic terminal. Remember that K^+ efflux through opened K^+ channels hastens the return to resting potential (repolarization) during the falling phase of the action potential. Because the presence of a local action potential is responsible for the opening of K^+ channels in the terminal, a prolonged action potential permits the greater K^+ influx associated with sensitization.

▶ **FIGURE 3-30 Habituation and sensitization in *Aplysia*.** Researchers have shown that in the sea snail *Aplysia*, two forms of short-term memory—habituation and sensitization—result from opposite changes in neurotransmitter release from the same presynaptic neuron, caused by different transient channel modifications.

Thus, existing synaptic pathways may be functionally interrupted (habituated) or enhanced (sensitized) during simple learning. Scientists speculate that much of short-term memory is similarly a temporary modification of already existing processes. Several lines of research suggest that the cyclic AMP cascade, especially activation of protein kinase, plays an important role, at least in elementary forms of learning and memory.

Further studies have revealed that declarative memories, which involve conscious awareness and are more complex than habituation and sensitization, are initially stored by means of more persistent changes in activity of existing synapses. Specifically, initial storage of declarative information appears to be accomplished by means of long-term potentiation, to which we now turn our attention.

MECHANISM OF LONG-TERM POTENTIATION

The term **long-term potentiation (LTP)** refers to a prolonged increase in the strength of existing synaptic connections in activated pathways following brief periods of repetitive stimulation. LTP has been shown to last for days or even weeks—long enough for this short-term memory to be consolidated into more permanent long-term memory. LTP is especially prevalent in the hippocampus, a site critical for converting short-term memories into long-term memories. When LTP occurs, simultaneous activation of both the presynaptic and postsynaptic neurons across a given excitatory synapse results in long-lasting modifications that enhance the ability of the presynaptic neuron to excite the postsynaptic neuron. Because both the presynaptic and postsynaptic neurons must be active at the same time, the development of LTP is restricted to the pathway that is stimulated. Pathways between other inactive presynaptic inputs and the same postsynaptic cell are not affected. With LTP, signals from a given presynaptic neuron to a postsynaptic neuron become stronger with repeated use. Keep in mind that strengthening of synaptic activity results in the formation of more EPSPs in the postsynaptic neuron in response to chemical signals from this particular excitatory presynaptic input. This increased excitatory responsiveness is ultimately translated into more action potentials being sent along this postsynaptic cell to other neurons.

Enhanced synaptic transmission could theoretically result from either changes in the postsynaptic neuron (such as increased responsiveness to the neurotransmitter) or in the presynaptic neuron (such as increased release of neurotransmitter). The underlying mechanisms for LTP are still the subject of much research and debate. Most likely, multiple mechanisms are involved in this complex phenomenon. Based on current scientific evidence, here are two plausible proposals, one involving a postsynaptic change and the other a presynaptic modification (▶ Figure 3-31).

The first proposed mechanism involves increased responsiveness of the postsynaptic cell. In this proposal, the presynaptic neuron releases glutamate, an excitatory neurotransmitter, which binds with two types of glutamate receptors in the postsynaptic neuron's plasma membrane—**NMDA receptors** and **AMPA receptors**. Because *NMDA receptors* act as nonselective cation channels, their activation and opening on binding with glutamate leads to K^+ as well as K^+ entry into the postsynaptic cell.

The entering calcium activates a K^+ second-messenger pathway in the postsynaptic neuron. This second-messenger pathway leads to the physical insertion of additional AMPA receptors in the postsynaptic membrane. **AMPA receptors** are primarily responsible for generating EPSPs in response to glutamate activation. Because of this increased availability of AMPA receptors, the postsynaptic cell exhibits a greater EPSP response to subsequent release of glutamate from the presynaptic cell. This heightened sensitivity of the postsynaptic neuron to glutamate from the presynaptic cell helps maintain LTP.

A second proposed mechanism involves increased neurotransmitter release from the presynaptic cell as a major contributor to LTP. In this proposed mechanism, activation of the K^+ second-messenger pathway in the postsynaptic neuron causes this postsynaptic cell to release a retrograde factor that diffuses to the presynaptic neuron. Here, the retrograde factor activates a second-messenger system in the presynaptic neuron, ultimately enhancing the release of glutamate from the presynaptic neuron. This positive feedback strengthens the signalling process at this synapse, helping sustain LTP. Note that in this mechanism for the development of LTP, a chemical factor from the postsynaptic neuron influences the presynaptic neuron—exactly the opposite direction of neurotransmitter activity at a synapse. Synapses traditionally operate unidirectionally, with the presynaptic neuron releasing a neurotransmitter that influences the postsynaptic neuron. The cell body and dendrites of the postsynaptic neuron do not contain any transmitter vesicles. Therefore, the retrograde factor is distinct from classical neurotransmitters or **neuropeptides**. Most investigators believe that the retrograde messenger is **nitric oxide**, a chemical that recently has been found to perform a bewildering array of other functions in the body. These other functions range from dilation of blood vessels in the penis during erection to destruction of foreign invaders by the immune system (p. 463).

Studies suggest a regulatory role for the cAMP second-messenger pathway in the development and maintenance of LTP, in addition to the K^+ second-messenger pathway. Participation of cAMP may hold a key to linking short-term memory to long-term memory consolidation.

Long-term memory

Whereas short-term memory involves transient strengthening of pre-existing synapses, long-term memory storage requires the activation of specific genes that control the synthesis of proteins needed for lasting structural or functional changes at specific synapses. Examples of such changes include the formation of new synaptic connections or permanent changes in presynaptic or postsynaptic membranes. Thus, long-term memory involves permanent physical changes in the brain.

The brains of experimental animals reared in a sensory-deprived environment are observably different at a microscopic level from animals raised in a sensory-rich environment. The animals afforded more environmental interactions—and supposedly, therefore, more opportunity to learn—displayed greater branching and elongation of dendrites in nerve cells in regions of the brain suspected to be involved with memory storage. Greater

FIGURE 3-31 Possible pathways for long-term potentiation

dendritic surface area presumably provides more sites for synapses. This means long-term memory may be stored at least in part by a particular pattern of dendritic branching and synaptic contacts.

A positive regulatory protein, **CREB**, is the molecular switch that activates (turns on) the genes important in long-term memory storage. Another related molecule, **CREB2**, is a repressor of CREB-facilitated protein synthesis. Formation of enduring memories involves not only the activation of positive regulatory factors (CREB) that favour memory storage but also the turning off of inhibitory constraining factors (CREB2) that prevent memory storage. The shifting balance between positive

and repressive factors is believed to ensure that only information relevant to the individual, not everything encountered, is put into long-term storage.

The mechanism that activates CREB and inhibits CREB2 is still unknown, but may be associated with cAMP activating CREB. This second messenger plays a regulatory role in LTP as well as in simpler forms of short-term memory, such as sensitization. Furthermore, cAMP can activate CREB, which ultimately leads to new protein synthesis and the consolidation of long-term memory. Consolidation of both declarative and procedural memories depends on CREB (and presumably CREB2). CREB serves as a common molecular switch for converting both these

categories of memory from the transient short-term to the permanent long-term mode.

The CREB regulatory proteins regulate a group of genes, the **immediate early genes (IEGs)**, which play a critical role in memory consolidation. These genes govern the synthesis of the proteins that encode long-term memory. The exact role that these critical new long-term memory proteins might play remains speculative. They may be needed for structural changes in dendrites or used for synthesis of more neurotransmitters or additional receptor sites. Alternatively, they may accomplish long-term modification of neurotransmitter release by sustaining biochemical events initially activated by short-term memory processes.

To complicate the issue even further, numerous hormones and neuropeptides are known to affect learning and memory processes.

Check Your Understanding 3.7

1. Define *consolidation*.
2. Compare the molecular mechanisms for short-term and long-term memories.
3. Distinguish among declarative memories, procedural memories, and working memory, and indicate the brain area primarily associated with each.

Language

Language ability is an excellent example of early cortical plasticity coupled with later permanence. Unlike the sensory and motor regions of the cortex, which are present in both hemispheres, in the vast majority of people the areas of the brain responsible for language ability are found in only one hemisphere—the left.

However, if a child under the age of two accidentally suffers damage to the left hemisphere, language functions are transferred to the right hemisphere with no delay in language development, but at the expense of less obvious nonverbal abilities for which the right hemisphere is normally responsible. Up to about the age of 10, after damage to the left hemisphere, language ability can usually be re-established in the right hemisphere following a temporary period of loss. If damage occurs beyond the early teens however, language ability is permanently impaired, even though some limited restoration may be possible. The regions of the brain involved in comprehending and expressing language apparently are permanently assigned before adolescence.

Even in normal, healthy individuals, there is evidence for early plasticity and later permanence in language development. Infants can distinguish between and articulate the entire range of speech sounds, but each language uses only a portion of these sounds. As children mature, they often lose the ability to distinguish between or express speech sounds that are not important in their native language. For example, Japanese children can distinguish between the sounds of “r” and “l,” but many Japanese adults cannot perceive the difference between them.

ROLES OF BROCA’S AREA AND WERNICKE’S AREA

Language is a complex form of communication in which written or spoken words symbolize objects and convey ideas. It involves the integration of two distinct capabilities—namely, *expression* (speaking ability) and *comprehension*—each of which is related to a specific area of the cortex. The primary areas of cortical specialization for language are Broca’s area and Wernicke’s area. **Broca’s area**, which governs speaking ability, is located in the left frontal lobe in close association with the motor areas of the cortex that control the muscles necessary for articulation (Figure 3-32; see also Figures 3-23a and 3-23b). **Wernicke’s area**, located in the left cortex at the juncture of the parietal, temporal, and occipital lobes, is concerned with language comprehension. It plays a critical role in understanding both spoken and written messages. Furthermore, it is responsible for formulating coherent patterns of speech that are transferred via a bundle of fibres to Broca’s area, which in turn controls articulation of this speech. Wernicke’s area receives input from the visual cortex in the occipital lobe, a pathway important in reading comprehension and in describing objects seen, as well as from the auditory cortex in the temporal lobe, a pathway essential for understanding spoken words. Wernicke’s area also receives input from the somatosensory cortex, a pathway important in the ability to read Braille. Precise interconnecting pathways between these localized cortical areas are involved in the various aspects of speech (Figure 3-32).

Clinical Connections

Jackie became alerted that she had a serious medical problem when her speech became slurred. However, since she had no problem understanding speech, it was more likely that one of her lesions was in or near Broca’s area. That said, the control of speech integrates many areas of the brain, and you always need to think of other causes that could result in the same effect.

LANGUAGE DISORDERS

Because various aspects of language are localized in different regions of the cortex, damage to specific regions of the brain can result in selective disturbances of language. Damage to Broca’s area results in a failure of word formation, although the patient can still understand the spoken and written word. Such people know what they want to say but cannot express themselves. Even though they can move their lips and tongue, they cannot establish the proper motor command to articulate the desired words. In contrast, patients with a lesion in Wernicke’s area cannot understand words they see or hear. They can speak fluently, even though their perfectly articulated words make no sense. They cannot attach meaning to words or choose appropriate words to convey their thoughts. Such language disorders caused by damage to specific cortical areas are known as **aphasias**, most of which result from strokes. Aphasias should not be confused with **speech impediments**, which are caused by a defect in the mechanical aspect of speech, such as weakness or incoordination of the muscles controlling the vocal apparatus.

Dyslexia, another language disorder, is a difficulty in learning to read because of inappropriate interpretation of

1a To speak about something seen, the brain transfers the visual information from the primary visual cortex to the angular gyrus of the parietal-temporal-occipital association cortex, which integrates inputs such as sight, sound, and touch.

1b To speak about something heard, the brain transfers the auditory information from the primary auditory cortex to the angular gyrus.

2 The information is transferred to Wernicke's area, where the choice and sequence of words to be spoken are formulated.

3 This language command is then transmitted to Broca's area, which translates the message into a programmed sound pattern.

4 This sound program is conveyed to the precise areas of the primary motor cortex that activate the appropriate facial and tongue muscles for causing the desired words to be spoken.

FIGURE 3-32 Cortical pathway for speaking a written word or naming a visual object. The grey arrows and squared numbers with accompanying explanation indicate the pathway used to speak about something seen. Similarly, appropriate muscles of the hand can be commanded to write the desired words.

words. The problem arises from developmental abnormalities in connections between the visual and language areas of the cortex or within the language areas themselves; that is, the person with dyslexia is born with altered neuronal pathways within the language-processing system. Emerging evidence suggests that dyslexia stems from a deficit in phonological processing, meaning an impaired ability to break down written words into their underlying phonetic components. Dyslexics have difficulty decoding and thus identifying and assigning meaning to words. The condition is in no way related to intellectual ability.

The association areas

The motor, sensory, and language areas account for only about half of the total cerebral cortex. The remaining areas, called **association areas**, are involved in higher functions. There are three association areas: (1) the *prefrontal association cortex*, (2) the *parietal-temporal-occipital association cortex*, and (3) the *limbic association cortex* (see Figure 3-23a). At one time the association areas were called “silent areas” because stimulation does not produce any observable motor response or sensory perception. (During brain surgery, typically the patient remains awake and only local anaesthetic is used along the cut scalp. This is possible because the brain itself is insensitive to pain. Before cutting into this precious, nonregenerative tissue, the neurosurgeon explores the exposed region with a tiny stimulating electrode. The patient is asked to describe what happens with each stimulation—the flick of a finger, a prickly feeling on the bottom of the foot, nothing? In this way, the surgeon can ascertain the appropriate landmarks on the neural map before making an incision.)

The **prefrontal association cortex** is the front portion of the frontal lobe, just anterior of the premotor cortex. This is the part

of the brain that “brainstorms.” Specifically, the roles attributed to this region are (1) planning for voluntary activity, (2) decision making (i.e., weighing consequences of future actions and choosing between different options for various social or physical situations) (see Figure 3-23b), (3) creativity, and (4) personality traits. To carry out these highest of neural functions, the prefrontal cortex is the site of operation of working memory, where the brain temporarily stores and actively manipulates information used in reasoning and planning.

Stimulating the prefrontal cortex does not produce any observable effects, but deficits in this area change personality and social behaviour. Because damage to the prefrontal lobe was known to produce these changes, about 70 years ago prefrontal lobotomy (surgical removal) was used for treating violent individuals or others with so-called bad personality traits or social behaviour, in the hopes that their personality change would be for the better. Of course, the other functions of the prefrontal cortex were lost in the process (fortunately, the technique was used for only a short time).

The **parietal-temporal-occipital association cortex** lies at the interface of the three lobes for which it is named. In this strategic location, it pools and integrates somatic, auditory, and visual sensations projected from these three lobes for complex perceptual processing. It enables you to “get the complete picture” of the relationship of various parts of your body with the external world. For example, it integrates visual information with proprioceptive input to let you place what you are seeing in proper perspective, such as realizing that a bottle is in an upright position despite the angle from which you view it (i.e., whether you are standing up, lying down, or hanging upside down from a tree branch). This region is also involved in the language pathway connecting Wernicke's area to the visual and auditory cortices.

The **limbic association cortex** is located mostly on the bottom and adjoining the inner portion of each temporal lobe. This area is concerned primarily with motivation and emotion and is extensively involved in memory.

The cortical association areas are all interconnected by bundles of fibres within the cerebral white matter. Collectively, the association areas integrate diverse information for purposeful action. An oversimplified basic sequence of linkage between the various functional areas of the cortex is schematically represented in ▶ Figure 3-33.

The cerebral hemispheres

The cortical areas described so far appear to be equally distributed in both the right and left hemispheres, except for the language areas, which are found only on one side, usually the left. The left side is also most commonly the dominant hemisphere for fine motor control. Most people are right-handed, because the left side of the brain controls the right side of the body. Furthermore, each hemisphere is somewhat specialized in the types of mental activities it carries out best. The **left cerebral hemisphere** excels in logical, analytic, sequential, and verbal tasks, such as math, language forms, and philosophy. In contrast, the **right cerebral hemisphere** excels in non-language skills, especially spatial perception and artistic and musical talents. Whereas the left hemisphere tends to process information in a fine-detail, fragmentary way, the right hemisphere views the world in a big-picture, holistic way. Normally, much sharing of information occurs between the two hemispheres so that they complement each other, but in many individuals the skills associated

with one hemisphere are more strongly developed. Left cerebral hemisphere dominance tends to be associated with “thinkers,” whereas the right hemispheric skills dominate in “creators.”

3.12 Sleep: An Active Process

The term **consciousness** refers to subjective awareness of the external world and self, including awareness of the private inner world of one’s own mind—that is, awareness of thoughts, perceptions, dreams, and so on. Even though the final level of awareness resides in the cerebral cortex and a crude sense of awareness is detected by the thalamus, conscious experience depends on the integrated functioning of many parts of the nervous system.

The following states of consciousness, are listed in decreasing order of arousal level, based on the extent of interaction between peripheral stimuli and the brain:

- Maximum alertness
- Wakefulness
- Sleep (stages 1–4 and paradoxical)
- Coma

Maximum alertness depends on attention-getting sensory input that stimulates the reticular activating system (RAS) and subsequently the activity level of the CNS as a whole. At the other extreme, coma is the total unresponsiveness of a living person to external stimuli, caused either by brain stem damage that interferes with the RAS or by widespread depression of the cerebral cortex, for example, as a result of oxygen deprivation.

The **sleep–wake cycle** is a normal cyclic variation in awareness of surroundings. In contrast to being awake, sleeping people are not consciously aware of the external world, but they do have inward conscious experiences, such as dreams. Furthermore, they can be aroused by external stimuli, such as an alarm going off.

Sleep is an active process, not just the absence of wakefulness. Sleep is characterized by a decreased reaction to external stimuli, reduced voluntary movement, increased rate of anabolism, and a decreased rate of catabolism. The brain’s overall level of activity is not reduced during sleep. During certain stages of sleep, oxygen uptake by the brain is even increased above normal waking levels.

There are two types of sleep, characterized by different EEG patterns and different behaviours: *slow-wave sleep* (delta-wave; non-rapid eye movement, NREM) and *paradoxical sleep* (rapid eye movement, REM) (▶ Table 3-4).

EEG patterns during sleep

Slow-wave sleep occurs in four stages, each displaying a progressively lower frequency of EEG wave but higher in amplitude (▶ Figure 3-34). At the onset of sleep, you move through the stages of slow-wave sleep from light sleep (stage 1) to deep sleep (stage 4) during about a 30- to 45-minute period; you then reverse through the same stages in the same amount of time. A 10- to 15-minute episode of **paradoxical sleep** punctuates the end of each slow-wave sleep cycle. Paradoxically, your EEG

For simplicity, a number of interconnections have been omitted.

▶ **FIGURE 3-33** Schematic linking of various regions of the cortex

TABLE 3-4 Comparison of Slow-Wave and Paradoxical Sleep

TYPE OF SLEEP		
Characteristic	Slow-Wave Sleep	Paradoxical Sleep
EEG	Displays slow waves	Similar to EEG of alert, awake person
Motor activity	Considerable muscle tone; frequent shifting	Abrupt inhibition of muscle tone; no movement
Heart rate, respiratory rate, blood pressure	Minor reductions	Irregular
Dreaming	Rare (mental activity is extension of waking-time thoughts)	Common
Arousal	Sleeper easily awakened	Sleeper hard to arouse but apt to wake up spontaneously
Percentage of sleeping time	80 percent	20 percent
Other important characteristics	Has four stages; sleeper passes through this type of sleep first	Rapid eye movements

© 2016 Cengage

3

pattern during this time abruptly becomes similar to that of a wide-awake, alert individual, even though you are still asleep (hence, *paradoxical* sleep) (Figure 3-34). After the paradoxical episode, the stages of slow-wave sleep repeat.

A person cyclically alternates between the two types of sleep throughout the night. In a normal sleep cycle, you always pass through slow-wave sleep before entering **paradoxical** sleep. On average, paradoxical sleep occupies 20 percent of total sleeping time throughout adolescence and most of adulthood. Infants spend considerably more time in paradoxical sleep. In contrast,

paradoxical as well as deep, stage 4, slow-wave sleep declines in the elderly. People who require less total sleeping time than normal spend proportionately more time in the lighter stages of slow-wave sleep.

Behavioural patterns during sleep

In addition to distinctive EEG patterns, the two types of sleep are distinguished by behavioural differences. It is difficult to pinpoint exactly when an individual drifts from drowsiness into slow-wave sleep. In this type of sleep, the person still has considerable muscle tone and frequently shifts body position. Only minor reductions in respiratory rate, heart rate, and blood pressure occur. During this time the sleeper can be easily awakened and rarely dreams. The mental activity associated with slow-wave sleep is less visual than dreaming. It is more conceptual and plausible—like an extension of waking-time thoughts concerned with everyday events—and it is less likely to be recalled. The major exception is nightmares, which occur during stages 3 and 4. People who walk and talk in their sleep do so during slow-wave sleep.

The behavioural pattern accompanying paradoxical sleep is marked by abrupt inhibition of muscle tone throughout the body. The muscles are completely relaxed, with no movement taking place. Paradoxical sleep is further characterized by *rapid eye movements*, hence the alternative name, REM sleep. Heart rate and respiratory rate become irregular, and blood pressure may fluctuate. Another characteristic of REM sleep is *dreaming*. The rapid

FIGURE 3-34 EEG patterns during wake and different types of slow-wave and paradoxical sleep. Note that the EEG pattern during paradoxical (REM) sleep is similar to that of an alert, awake person, whereas the pattern during slow-wave sleep displays distinctly different waves.

eye movements are not related to “watching” the dream imagery. The eye movements are driven in a locked, oscillating pattern, uninfluenced by dream content.

Brain imaging of volunteers during REM sleep shows heightened activity in the higher-level visual-processing areas and limbic system (the seat of emotions), coupled with reduced activity in the prefrontal cortex (the seat of reasoning). This pattern of activity lays the groundwork for the characteristics of dreaming: internally generated visual imagery reflecting activation of the person’s “emotional memory bank” with little guidance or interpretation from the complex thinking areas. As a result, dreams are often charged with intense emotions, a distorted sense of time, and bizarre content, which, at the time of dreaming, is uncritically accepted as real and involves little reflection about all the strange happenings.

3

Check Your Understanding 3.8

1. Define *consciousness*.
2. Discuss the location and functions of the three neural systems that play a role in the sleep–wake cycle.

Chapter in Perspective: Focus on Homeostasis

To interact in appropriate ways with the external environment to sustain the body’s viability, such as in acquiring food, and to make the internal adjustments necessary to maintain homeostasis, the body must be informed about any changes taking place in the external and internal environments, be able to process this information, and send messages to various muscles and glands to accomplish the desired results. The nervous system, one of the body’s two major regulatory systems, plays a central role in this life-sustaining communication. The central nervous system (CNS), which consists of the brain and spinal cord, receives information about the external and internal environments by means of the afferent peripheral nerves. After sorting, processing, and integrating this input, the CNS

sends directions, by means of efferent peripheral nerves, to bring about appropriate muscular contractions and glandular secretions.

With its swift electrical signalling system, the nervous system is especially important in controlling the rapid responses of the body. Many neurally controlled muscular and glandular activities are aimed toward maintaining homeostasis. The CNS is the main site of integration between afferent input and efferent output. It links the appropriate response to a particular input so that conditions compatible with life are maintained in the body. For example, when informed by the afferent nervous system that blood pressure has fallen, the CNS sends appropriate commands to the heart and blood vessels to increase the blood pressure to normal. Likewise, when informed that the body is overheated, the CNS promotes secretion of sweat by the sweat glands. Evaporation of sweat helps cool the body to normal temperature. Were it not for this processing and integrating ability of the CNS, maintaining homeostasis in an organism as complex as a human would be impossible.

At the simplest level, the spinal cord integrates many basic protective and evacuative reflexes that do not require conscious participation, such as withdrawing from a painful stimulus and emptying of the urinary bladder. In addition to serving as a more complex integrating link between afferent input and efferent output, the brain is responsible for the initiation of all voluntary movement, complex perceptual awareness of the external environment and self, language, and abstract neural phenomena, such as thinking, learning, remembering, consciousness, emotions, and personality traits. All neural activity—from the most private thoughts to commands for motor activity, from enjoying a concert to retrieving memories from the distant past—is ultimately attributable to propagation of action potentials along individual nerve cells and chemical transmission between cells.

During evolutionary development, the nervous system has become progressively more complex. Newer, more complicated, and more sophisticated layers of the brain have been piled on top of older, more primitive regions. Mechanisms for governing many basic activities necessary for survival are built into the older parts of the brain. The newer, higher levels progressively modify, enhance, or nullify actions coordinated by lower levels in a hierarchy of command, and they also add new capabilities. Many of these higher neural activities are not aimed toward maintaining life, but they add immeasurably to the quality of being alive.

Objective Questions (Answers in Appendix E, p. A-38)

1. The major function of the CSF is to nourish the brain. (*True or false?*)
2. In emergencies when oxygen supplies are low, the brain can perform anaerobic metabolism. (*True or false?*)
3. The hands and structures associated with the mouth have a disproportionately large share of representation in both the sensory cortex and the motor cortex. (*True or false?*)
4. The left cerebral hemisphere specializes in artistic and musical ability, whereas the right side excels in verbal and analytical skills. (*True or false?*)
5. The specific function a particular cortical region will carry out is permanently determined during embryonic development. (*True or false?*)
6. _____ is a decreased responsiveness to an indifferent stimulus that is repeatedly presented.
7. The process of transferring and fixing short-term memory traces into long-term memory stores is known as _____.
8. Afferent fibres enter through the _____ root of the spinal cord, and efferent fibres leave through the _____ root.
9. Using the answer code on the right, indicate which neurons are being described (a characteristic may apply to more than one class of neurons):

___ 1. have receptor at peripheral endings	(a) afferent neurons
___ 2. lie entirely within the CNS	(b) efferent neurons
___ 3. lie primarily within the peripheral nervous system	(c) interneurons
___ 4. innervate muscles and glands	
___ 5. cell body is devoid of presynaptic inputs	
___ 6. predominant type of neuron	
___ 7. responsible for thoughts, emotions, memory, etc.	

10. Using the answer code on the right, match the following:

- | | |
|--|-------------------------------|
| ___ 1. consists of nerves carrying information between the periphery and the CNS | (a) somatic nervous system |
| ___ 2. consists of the brain and spinal cord | (b) autonomic nervous system |
| ___ 3. division of the peripheral nervous system that transmits signals to the CNS | (c) central nervous system |
| ___ 4. division of the peripheral nervous system that transmits signals from the CNS | (d) peripheral nervous system |
| ___ 5. supplies skeletal muscles | (e) efferent division |
| ___ 6. supplies smooth muscle, cardiac muscle, and glands | (f) afferent division |

Written Questions

1. Discuss the function of each of the following: astrocytes, oligodendrocytes, ependymal cells, microglia, cranium, vertebral column, meninges, cerebrospinal fluid, and blood-brain barrier.
2. Compare the composition of white and grey matter.
3. Draw and label the major functional areas of the cerebral cortex, indicating the functions attributable to each area.
4. Discuss the function of each of the following parts of the brain: thalamus, hypothalamus, basal ganglia, limbic system, cerebellum, and brain stem.
5. Discuss the roles of Broca's area and Wernicke's area in language.
6. Compare short-term and long-term memory.
7. What is an electroencephalogram?
8. Distinguish between a monosynaptic and a polysynaptic reflex.

POINTS TO PONDER

(Explanations in Appendix E, p. A-38)

1. Special studies designed to assess the specialized capacities of each cerebral hemisphere have been performed on *split-brain* patients. In these people, the corpus callosum—the bundle of fibres that links the two halves of the brain—has been surgically cut to prevent the spread of epileptic seizures from one hemisphere to the other. Even though no overt changes in behaviour, intellect, or personality occur in these patients, because both hemispheres individually receive the same information, deficits are observable with tests designed to restrict information to one brain hemisphere at a time. One such test involves limiting a visual stimulus to only half of the brain. Because of a crossover in the nerve pathways from the eyes to the occipital cortex, the visual information to the right of a midline point is transmitted to only the left half of the brain, whereas visual information to the left of this point is received by only the right half of the brain. A split-brain patient presented with a visual stimulus that reaches only the left hemisphere accurately describes the object seen, but when a visual stimulus is presented to only the right hemisphere, the patient denies having seen anything. The right hemisphere does receive the visual input, however, as demonstrated by nonverbal tests. Even though split-brain patients deny having seen anything after an object is presented to the right hemisphere, they can correctly match the object by picking it out from among a number of objects, usually to their own surprise. What is your explanation of this finding?
2. What symptom is most likely to occur as the result of a severe blow to the back of the head?
 - a. Paralysis
 - b. Hearing impairment
 - c. Visual disturbances
 - d. Burning sensations
 - e. Personality disorders
3. Give examples of conditioned reflexes you have acquired.
4. The hormone insulin enhances the carrier-mediated transport of glucose into most of the body's cells but not into brain cells. The uptake of glucose from the blood by neurons does not depend on insulin. Knowing the brain's need for a continuous supply of blood-borne glucose, predict the effect that insulin excess would have on the brain.

3

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-38)

Julio D., who had recently retired, was enjoying an afternoon of playing golf when suddenly he experienced a severe headache and dizziness. These symptoms were quickly followed by numbness and partial paralysis on the upper right side of his

body, accompanied by an inability to speak. After being rushed to the emergency room, Julio was diagnosed as having suffered a stroke. Given the observed neurologic impairment, what areas of his brain were affected?

The Peripheral Nervous System

Body systems maintain homeostasis

Peripheral nervous system

Cells make up body systems

Homeostasis

The nervous and endocrine systems, as the body's two major regulatory systems, regulate many body activities aimed at maintaining a stable internal fluid environment.

Homeostasis is essential for survival of cells

Neurons

© Dr. Michael Delamoy/Getty Images

The nervous system is one of two major regulatory systems of the body. It consists of the central nervous system (CNS), composed of the brain and spinal cord, and the peripheral nervous system (PNS), composed of the afferent and efferent fibres that relay signals between the CNS and the periphery (other parts of the body).

The afferent division of the PNS detects, encodes, and transmits peripheral signals to the CNS, thus informing the CNS about the internal and external environment. This afferent

input (i.e., feedback) to the controlling centres of the CNS is essential to making adjustments in effector organs to maintain homeostasis. The efferent division of the PNS enables the CNS to make adjustments by controlling the activities of effector organs (e.g., muscles and glands) through transmitting signals *from* the CNS to these organs. Unrelated to homeostasis, the PNS allows for planned voluntary actions, such as skeletal muscle contraction.

- 4.10 Somatic nervous system
- 4.11 Neuromuscular junction

4.1 | Introduction

The peripheral nervous system (PNS) is the link between the periphery and the central nervous system (CNS). It consists of nerve fibres that transmit information via myelinated and unmyelinated neurons. The afferent division of the PNS senses (via various receptors) and sends (via neurons) information about both the internal and external environment to the CNS. The CNS receives this input (i.e., information), interprets it, and initiates a response that is carried out through the efferent division. The efferent division, under the direction of the CNS, serves to consciously control the activity of some effector organs (e.g., skeletal muscles), and also to subconsciously control various tissues and organs (e.g., smooth muscle in blood vessels).

The conscious control is exerted by the efferent division through the somatic nervous system, whereas the subconscious control is exerted through the autonomic nervous system. Neither is more important than the other.

■ Clinical Connections

Deborah is a 60-year-old female. She is obese and was diagnosed with type 2 diabetes mellitus at the age of 40. Despite recommendations to alter her diet and to exercise, she claimed that standing has become painful, and it is easier for her to order in food than to walk to the grocery store a few blocks away. Deborah also struggles to remember to take her medications. Due to all these factors, her blood sugar levels are chronically elevated. Deborah used to be a very active knitter, but recently she had to stop because she struggles

Continued

with the fine coordination. Interestingly, she increasingly noticed that when she accidentally poked herself with knitting needles, she didn't feel it. Deborah also realized she had progressive development of numbness in her fingers and toes, mild muscle weakness, more frequent unsteadiness on her feet, and problems with her vision. She attributed all these symptoms to aging and ignored them until she started to have occasional sharp pain in her toes while sleeping. Then she went to see her physician.

Given her symptoms, her physician suspected and confirmed diabetic peripheral neuropathy. Her elevated blood sugar levels had led to microvascular injury. When this occurs, the blood supply to nerves can become compromised and result in nerve injury or abnormal nerve function.

4.2 | The Peripheral Nervous System: Afferent Division

4

The afferent neurons, also called sensory or receptor neurons, carry nerve impulses (action potentials) from receptors or sense organs toward the CNS.

Sensory information (e.g., pain) is transmitted via afferent pathways from a peripheral receptor to the CNS with no noticeable delay. The stimulus is sensed in the brain and perceived (as pain) based on the location of the brain that is stimulated. The structure of the afferent neurons is such that they have a single long dendrite, a short axon, and a smooth rounded cell body. The dendrite is structurally and functionally similar to an axon. Immediately external to the spine are thousands of afferent cell bodies that are aggregated in a swell, the *dorsal root ganglion*.

This chapter opens with a description of the fight-or-flight response, as it pertains to sensation, to demonstrate the robust nature of our body, and how the divisions of the nervous system work in symphony to prepare for stressful circumstances.

Fight-or-flight response

When you perceive a threatening situation, your body readies itself to either fight or flee the situation. An example: While walking in the woods you hear the rustling of leaves and branches behind you. You stop and look—it's a bear. Do you run, back up slowly, or confront the bear, making yourself seem as threatening as possible? During this acute (short-term) stress response, unnecessary functions are temporarily slowed, and energy is diverted to other functions vital to survival. In general, stress can be physical (an altercation), psychological (unpleasant event), or emotional (anger). Afferent input is necessary to respond to stress, for arousal, perception, and determination of efferent output. Using the example of seeing a bear, the physiological adjustments to the stress associated with the afferent division of the PNS are as follows:

- The afferent division provides information (sound, sight, smell) to the CNS about the external environment that influences conscious activity (i.e., decision making). Arousal occurs, which adjusts efferent output (e.g., muscles, heart rate).

- Hearing the rustling of leaves and branches, you quickly turn your head in the direction of the sounds. This requires the ears to sense and transmit the sound waves more quickly on the side of the body closest to the sound.
- To focus on the bear, your eyes use accommodation to provide a clear, crisp image.
- Pupils dilate to allow in more light.
- The decision to fight or flee in this situation is most likely based on your ability to judge distance. If the bear is close, you may not run, but if the bear is far off, you may decide to run. This requires cognitive processing and also good eye sight.

We return to this example in our discussion of the autonomic and efferent divisions' contributions to the fight-or-flight response later in this chapter (p. 187). Staying with the afferent division, we now examine somatosensation in detail.

Somatosensation

The somatosensory system consists of receptors (PNS) and processing centres (CNS) that integrate and create the sensory modalities (e.g., pain, temperature). The modality of the stimulus is determined by which sensory neuron is activated and where the stimulus terminates in the brain. The primary somatosensory area is located in the parietal lobes of the cerebral cortex. The somatosensory system reacts to diverse stimuli by means of four primary types of receptors: thermoreceptors, mechanoreceptors, photoreceptors, and chemoreceptors. These receptors are located throughout the body. Sensory information is transmitted in the form of an action potential from the receptors via sensory nerves (afferents) through tracts in the spinal cord to the brain. The system works when a receptor is stimulated (e.g., heat) and information is passed along the sensory neuron to an area in the brain uniquely attributed to that area on the body.

Sensation: Internal and external

Afferent information about the internal environment, such as blood pressure and concentration of carbon dioxide in the body fluids, never reaches the level of conscious awareness, but this input is essential for determining the appropriate efferent output to maintain homeostasis. The incoming pathway for information derived from the internal viscera (*viscera* are organs in the body cavities, such as the abdominal cavity) is called a **visceral afferent**. Even though mostly subconscious information is transmitted via visceral afferents, people do become aware of pain signals arising from the viscera.

In contrast, afferent input derived from receptors located at the body surface or in the muscles or joints typically reaches the level of conscious awareness. Final processing of sensory input by the CNS not only is essential for interaction with the environment for basic survival (e.g., fight-or-flight) but also adds immeasurably to the richness of life. This input is known as *sensory information*, and the incoming pathway is considered a **sensory afferent**. Sensory information is categorized as either (1) **somatic sensation** (body sense) arising from the body surface, including *somaesthetic sensation* from the skin and *proprioception*

from the muscles, joints, skin, and inner ear or (2) **special senses**, including *vision, hearing, taste, smell, and equilibrium*.

Perception: Conscious awareness of surroundings

Perception is the conscious interpretation of the external world as created by the brain from a pattern of nerve impulses delivered to it from sensory receptors. Is the world, as we perceive it, reality? The answer is a resounding no. Our perception is different from what is really “out there,” for several reasons. First, humans have receptors that detect only a limited number of existing energy forms. We perceive sounds, colours, shapes, textures, smells, tastes, and temperature but are not informed of magnetic forces, polarized light waves, radio waves, or X-rays because we do not have receptors to respond to these other energy forms. What is not detected by receptors, the brain will never know. There are several reasons for this. First, our response range is limited even for the energy forms for which we do have receptors. For example, dogs can hear a whistle whose pitch is above our level of detection. Second, the information channels to our brains are not high-fidelity recorders. During precortical processing of sensory input, some features of stimuli are accentuated, and others are suppressed or ignored. Third, the cerebral cortex further manipulates the data—comparing the sensory input with other incoming information as well as with memories of past experiences—to extract the significant features: for example, sifting out a friend’s words from the hubbub of sound in a school cafeteria. In the process, the cortex often fills in or distorts the information to abstract a logical perception; that is, it “completes the picture.” As a simple example, in ▶ Figure 4-1a you “see” a white square even though there is no white square, but merely right-angle wedges taken out of four red circles. Optical illusions illustrate how the brain interprets reality according to its own rules. Do you see two faces in profile or a wine glass in ▶ Figure 4-1b? You can alternately see one or the other out of identical visual input. Thus, our perceptions do not replicate reality. Other species, equipped with different types of receptors and sensitivities and with different neural processing, perceive a markedly different world from what we perceive.

▶ **FIGURE 4-1 Optical illusions.** (a) Do you “see” a white square that is not really there? (b) Variable perceptions from the same visual input. Do you see two faces in profile, or a wine glass?

4.3 Receptor Physiology

An afferent neuron has a receptor at its peripheral ending that responds to a stimulus in both the external and internal environments. A stimulus is a change detectable by the body that meets a minimum threshold. Stimuli exist in a variety of energy forms, such as heat, light, sound, pressure, and chemical changes. Receptors vary widely in complexity, and their axons can be myelinated or unmyelinated. **Somatosensory receptors** such as free nerve endings consist of a neuron with an exposed receptor, whereas the **special senses receptor** in the ear turns a mechanical stimulation (non-neural) into a neural signal by synapsing onto a sensory neuron. Because the only way afferent neurons can transmit information about these stimuli to the CNS is via action potential propagation, receptors must convert these other forms of energy into electrical signals. This energy-conversion process, known as **transduction**, converts the mechanical or chemical stimulation into an electrical signal through changes in ion permeability at controlled ion channels.

As all stimuli are converted to action potentials in sensory neurons, this would seem to present a problem for the CNS in distinguishing the various forms of stimuli. However, by using four basic properties of the stimuli, the CNS is able to accurately differentiate the incoming stimuli from the PNS. These properties include modality, intensity, location, and duration.

Adequate stimuli and threshold

Each type of receptor is specialized to respond best to one type of energy, known as an **adequate stimulus**. For example, receptors in the eye are most sensitive to light, receptors in the ear to sound waves, and warmth receptors in the skin to heat energy. Because of this differential sensitivity of receptors, we cannot see with our ears or hear with our eyes. Some receptors can respond weakly to stimuli other than their adequate stimulus, but even when activated by a different stimulus, a receptor still gives rise to the sensation usually detected by that receptor type. As an example, the adequate stimulus for eye receptors (photoreceptors) is light, to which they are exquisitely sensitive, but these receptors can also be activated to a lesser degree by mechanical stimulation. When hit in the eye, a person often “sees stars,” because the mechanical pressure stimulates the photoreceptors. Thus, the sensation perceived depends on the **modality** of receptor stimulated rather than on the type of stimulus. The minimum stimulus required to activate the receptor is known as the **threshold**.

TYPES OF RECEPTORS ACCORDING TO THEIR ADEQUATE STIMULUS

Depending on the type of energy to which they ordinarily respond, sensory receptors are categorized as follows:

- **Photoreceptors** are responsive to visible wavelengths of light.
- **Mechanoreceptors** are sensitive to mechanical energy. Examples include skeletal muscle receptors sensitive to stretch; the receptors in the ear that contain fine hair cells, which bend as a result of sound waves; blood pressure—monitoring baroreceptors; and osmoreceptors, which respond to stretch. Other stimuli sensed are vibration and acceleration.

- **Thermoreceptors** are sensitive to varying amounts of heat.
- **Chemoreceptors** are sensitive to specific chemicals. Chemoreceptors include the receptors for smell and taste, the chemical content of the digestive tract, and oxygen and carbon dioxide in the blood.

Some sensations are compound sensations, in that their perception arises from the central integration of several simultaneously activated primary sensory inputs. For example, the perception of wetness comes from touch, pressure, and thermal receptor input; there is no such thing as a “wetness receptor.”

USES OF INFORMATION DETECTED BY RECEPTORS

Information detected by receptors and conveyed via afferent neurons to the CNS is used for a variety of purposes:

- It is essential for the control of efferent output, both for regulating motor behaviour based on external and internal stimuli and also to direct and maintain homeostasis. At the most basic level, afferent input provides information (for use—consciously and subconsciously) for the CNS to use in directing activities necessary for survival (e.g., fight-or-flight response). We could not be aware of and interact successfully with our environment or with one another without sensory input.
- Processing of sensory input by the reticular activating system in the brain stem is critical for cortical arousal and consciousness (p. 112).
- Central processing of sensory information gives rise to our perceptions of the world around us.
- Selected information delivered to the CNS may be stored for future reference.
- Sensory stimuli can have a profound impact on our emotions. The smell of just-baked apple pie, the sight of a loved one, hearing bad news—sensory input can gladden, sadden, arouse, calm, anger, frighten, or evoke a wide range of emotions.

We now examine how adequate stimuli initiate action potentials that ultimately are used for these purposes.

Stimuli and receptor permeability

A receptor may be either (1) a specialized ending of the afferent neuron or (2) a separate receptor cell closely associated with the peripheral ending of the neuron. Stimulation of a receptor alters its membrane permeability, usually by causing a nonselective opening of all small ion channels. The means by which this permeability change takes place is individualized for each receptor type. Because the electrochemical driving force is greater for sodium (Na^+) than for other small ions at resting potential, the predominant effect is an inward flux of Na^+ , which depolarizes the receptor membrane (p. 59). (There are exceptions; for example, photoreceptors are hyperpolarized upon stimulation.) This local depolarizing change in potential is known as a **generator potential**, if the receptor is a specialized ending of an afferent neuron, or as a **receptor potential**, in the case of a separate receptor cell. The receptor (or generator) potential is a graded potential whose amplitude and **duration** can vary,

depending on the strength and the rate of application or removal of the stimulus (p. 59). The stronger the stimulus, the greater is the change in ion permeability, and the larger the receptor potential. As is true of all graded potentials, receptor potentials have no refractory period, so summation in response to rapidly successive stimuli is possible. Because the receptor region has a very high threshold, action potentials do not take place at the receptor itself. For long-distance transmission, the receptor potential must be converted into action potentials that can be propagated along the afferent fibre.

Receptor potentials and action potentials

If a receptor (or generator) potential has sufficient magnitude, it may initiate an action potential in the afferent neuron membrane next to the receptor by triggering the opening of Na^+ channels in this region. The means by which the Na^+ channels are opened differ depending on whether the receptor is a separate receptor cell or a specialized afferent ending.

- In the case of a separate receptor cell, a receptor potential triggers the release of a chemical messenger that diffuses across the small space separating the receptor cell from the ending of the afferent neuron, similar to a synapse (► Figure 4-2a). Binding of the chemical messenger with specific protein receptor sites on the afferent neuron membrane opens chemically gated Na^+ channels (p. 58).
- In the case of a specialized afferent ending, local current flow between the activated receptor ending undergoing a generator potential and the cell membrane adjacent to the receptor brings about opening of voltage-gated Na^+ channels in this adjacent region (► Figure 4-2b).

In either case, if the magnitude of the resulting ionic flux is big enough to bring the adjacent membrane to threshold, an action potential is initiated and self-propagates along the afferent fibre to the CNS. (For convenience, from here on we will refer to both receptor potentials and generator potentials as receptor potentials.)

Note that the initiation site of action potentials in an afferent neuron differs from the site in an efferent neuron or interneuron. In the latter two types of neurons, action potentials are initiated at the axon hillock located at the start of the axon next to the cell body (p. 64). By contrast, action potentials are initiated at the peripheral end of an afferent nerve fibre next to the receptor, a long distance from the cell body (► Figure 4-3).

The **intensity** of the stimulus is reflected by the magnitude of the receptor potential. In turn, the larger the receptor potential is, the greater the frequency of action potentials generated in the afferent neuron. A larger receptor potential cannot bring about a larger action potential (because of the all-or-none law), but it can induce more rapid firing of action potentials (p. 59). Stimulus strength is also reflected by the size of the area stimulated. Stronger stimuli usually affect larger areas, so correspondingly more receptors respond. For example, a light touch does not activate as many pressure receptors in the skin as does a more forceful touch applied to the same area. Stimulus intensity is therefore distinguished both by the frequency of action potentials generated in the afferent neuron and by the number of receptors activated within the area (see Why It Matters).

(a) Receptor potential in specialized afferent ending

- 1 In sensory receptors that are specialized afferent neuron endings, stimulus opens stimulus-sensitive channels, permitting net Na^+ entry that produces receptor potential.
- 2 Local current flow between depolarized receptor ending and adjacent region opens voltage-gated Na^+ channels.
- 3 Na^+ entry initiates action potential in afferent fibre that self-propagates to CNS.

(b) Receptor potential in separate receptor cell

- 1 In sensory receptors that are separate cells, stimulus opens stimulus-sensitive channels, permitting net Na^+ entry that produces receptor potential.
- 2 This local depolarization opens voltage-gated Ca^{2+} channels.
- 3 Ca^{2+} entry triggers exocytosis of neurotransmitter.
- 4 Neurotransmitter binding opens chemically gated receptor channels at afferent ending, permitting net Na^+ entry.
- 5 Resultant depolarization opens voltage-gated Na^+ channels in adjacent region.
- 6 Na^+ entry initiates action potential in afferent fibre that self-propagates to CNS.

► **FIGURE 4-2 Conversion of receptor potential into action potentials.** (a) Specialized afferent ending as sensory receptor. Local current flow between a depolarized receptor ending undergoing a receptor potential and the adjacent region initiates an action potential in the afferent fibre by opening voltage-gated Na^+ channels. (b) Separate receptor cell as sensory receptor. The depolarized receptor cell undergoing a receptor potential releases a neurotransmitter that binds with chemically gated channels in the afferent fibre ending. This binding leads to a depolarization that opens voltage-gated Na^+ channels, initiating an action potential in the afferent fibre.

Clinical Connections

Recall that Deborah was experiencing numbness in her fingers and toes. In diabetic peripheral neuropathy, the longer afferent nerves are affected first, which is why she was experiencing numbness in the extremities. In her case, some afferent nerves in her fingers and toes were injured and were unable to initiate or propagate action potentials in response to touch. While this is an example of mechanoreceptors being affected, those with diabetic neuropathy can also experience injury to other receptor types. For example, when thermoreceptor afferent neurons are damaged, the sense of heat or cold can be lost. When this happens, someone who touches a hot surface may not withdraw their hand in time to prevent serious burning.

Adaptation to sustained stimulation

Stimuli of the same intensity do not always bring about receptor potentials of the same magnitude from the same receptor. Some receptors can diminish the extent of their depolarization despite sustained stimulus strength—a phenomenon called **adaptation**. Subsequently, the frequency of action potentials generated in the

afferent neuron decreases. That is, the receptor “adapts” to the stimulus by no longer responding to it to the same degree.

TYPES OF RECEPTORS ACCORDING TO THEIR SPEED OF ADAPTATION

There are two types of receptors—*tonic receptors* and *phasic receptors*—based on their speed of adaptation. **Tonic receptors** do not adapt at all, or they adapt slowly (► Figure 4-4a). These receptors are important in situations where it is valuable to maintain information about a stimulus. Examples of tonic receptors are muscle stretch receptors, which monitor muscle length, and joint proprioceptors, which measure the degree of joint flexion. To maintain posture and balance, the CNS must continually get information about the degree of muscle length and joint position. It is important, therefore, that these receptors do not adapt to a stimulus but continue to generate action potentials to relay this information to the CNS.

Phasic receptors, in contrast, are rapidly adapting receptors. The receptor rapidly adapts by no longer responding to a maintained stimulus, but when the stimulus is removed, the receptor typically responds with a slight depolarization called the **off response** (► Figure 4-4b). Phasic receptors are useful in

© 2016 Cengage

► **FIGURE 4-3** Comparison of the initiation site of an action potential in the three types of neurons.

situations where it is important to signal a change in stimulus intensity rather than to relay status quo information. Rapidly adapting receptors include *tactile (touch) receptors* in the skin that signal changes in pressure on the skin surface. Because these receptors adapt rapidly, you are not continually conscious of wearing your watch, rings, and clothing. For example, when you put something on, you soon become accustomed to it, due to these receptors' rapid adaptation. When you take the item off, you are aware of its removal, because of the off response.

Labelling somatosensory pathways

On reaching the spinal cord, afferent information has two possible destinies: (1) it may become part of a reflex arc, bringing about an appropriate effector response, or (2) it may be relayed

© 2016 Cengage

► **FIGURE 4-4** Tonic and phasic receptors. (a) Tonic receptor. This receptor type does not adapt at all or adapts slowly to a sustained stimulus, and thereby provides continuous information about the stimulus. (b) Phasic receptor. This receptor type adapts rapidly to a sustained stimulus and frequently exhibits an off response when the stimulus is removed. Thus, the receptor signals changes in stimulus intensity rather than relaying status quo information.

Why It Matters The Sense of Graded Potentials

A receptor potential is a type of graded potential (Chapter 2). It is generally a depolarizing event resulting from inward current flow. The influx of current often brings the membrane potential of the sensory receptor toward threshold, triggering an action potential. Receptor potentials therefore vary in size and, if frequent or large enough, will trigger an action potential. An example of a receptor is a taste bud, where taste, a chemical signal, is converted into an electrical signal and sent to the brain (specifically, the primary gustatory region). When stimulated, the taste bud triggers the release of a neurotransmitter through exocytosis of synaptic vesicles from the presynaptic membrane. The neurotransmitter molecules diffuse across the synaptic cleft to the postsynaptic membrane, where the excitatory stimulus continues to transmit the signal to the primary gustatory region of the brain. The sense of taste is equivalent to the excitation of the taste receptors, and receptors for a large number of specific chemicals have been identified. Researchers have grouped taste into five basic sensations: sweet, salty, sour, bitter, and umami (savory or meaty). All basic tastes are classified as either appealing or aversive, which can be beneficial to your health. If, for example, a serving of food has gone bad, your taste buds will often warn you prior to swallowing it. This warning will greatly reduce your likelihood of developing food poisoning.

upward to the brain via ascending pathways for further processing and possible conscious awareness. Pathways conveying conscious somatic sensation, the **somatosensory pathways**, consist of discrete chains of neurons, or **labelled lines**, synaptically interconnected in a particular sequence to accomplish progressively more sophisticated processing of the sensory information.

LABELLED LINES AND LOCATION OF STIMULUS

The afferent neuron with its peripheral receptor that first detects the stimulus is known as a **first-order sensory neuron**. It synapses on a **second-order sensory neuron**, either in the spinal cord or in the medulla, depending on which sensory pathway is involved. This neuron then synapses on a **third-order sensory neuron** in the thalamus, and so on. With each step, the input is processed further. A particular sensory modality (e.g., touch, sight, sound, pain) detected by a specialized receptor type is sent over a specific afferent and ascending pathway—a pathway committed to that modality—to excite a defined area in the somatosensory cortex. That is, a particular sensory input is projected to a specific location of the cortex (see ► Figure 4-24a, for an example). For example, if a free nerve ending associated with pain is stimulated, it does not matter if the stimulus is thermal, pressure, or chemical; the person perceives it as pain. In this way, different types of incoming information are kept separate within specific labelled lines between the periphery and the cortex. In this way, even though all information is propagated to the CNS via the same type of signal (action potentials), the brain can decode the type and location of the stimulus. ■ Table 4-1

TABLE 4-1 Coding of Sensory Information

Stimulus Property	Mechanism of Coding
Type of Stimulus (stimulus modality)	Distinguished by the type of receptor activated and the specific pathway over which this information is transmitted to a particular area of the cerebral cortex
Location of Stimulus	Distinguished by the location of the activated receptive field and the pathway that is subsequently activated to transmit this information to the area of the somatosensory cortex representing that particular location
Intensity of Stimulus (stimulus strength)	Distinguished by the frequency of action potentials initiated in an activated afferent neuron and the number of receptors (and afferent neurons) activated

© 2016 Cengage

summarizes how the CNS is informed of the type (what), location (where), and intensity (how much) of a stimulus.

PHANTOM PAIN

Activation of a sensory pathway at any point gives rise to the same sensation that would be produced by stimulation of the receptors in the body part itself. This phenomenon has served as the traditional explanation for **phantom pain**—for example, pain perceived as originating in the foot by a person whose leg has been amputated at the knee. Irritation of the severed endings of the afferent pathways in the stump can trigger action potentials that, on reaching the foot region of the somatosensory cortex, are interpreted as pain in the missing foot. New evidence suggests that, in addition, the sensation of phantom pain may arise from extensive remodelling of the brain region that originally handled sensations from the severed limb. This remapping of the vacated area of the brain is speculated to somehow lead to signals from elsewhere being misinterpreted as pain arising from the missing extremity.

Acuity, receptive field size, and lateral inhibition

Each somatosensory neuron responds to stimulus information only within a circumscribed region of the skin surface surrounding it; this region is called its **receptive field**. The size of a receptive field varies inversely with the density of receptors in the region; the more closely receptors of a particular type are spaced, the smaller the area of skin each monitors. The smaller the receptive field is in a region, the greater its **acuity**—that is, its **discriminative ability**. Compare the tactile discrimination in your fingertips with that in your elbow by “feeling” the same object with both. You can sense more precise information about the object with your richly innervated fingertips because the receptive fields

there are small; as a result, each neuron signals information about small, discrete portions of the object's surface. An estimated 17 000 tactile mechanoreceptors are present in the fingertips and palm of each hand. In contrast, the skin over the elbow is served by relatively few sensory endings with larger receptive fields. Subtle differences within each large receptive field cannot be detected. The distorted cortical representation of various body parts in the sensory homunculus (p. 118) corresponds precisely with the innervation density; more cortical space is allotted for sensory reception from areas with smaller receptive fields and, accordingly, greater tactile discriminative ability.

Besides receptor density, a second factor influencing acuity is **lateral inhibition**. You can appreciate the importance of this phenomenon by slightly indenting the surface of your skin with the point of a pencil (► Figure 4-5a). The receptive field is excited immediately under the centre of the pencil point where the stimulus is most intense, but the surrounding receptive fields are also stimulated, only to a lesser extent because they are less distorted. If information from these marginally excited afferent fibres in the fringe of the stimulus area were to reach the cortex, localization of the pencil point would be blurred. To facilitate localization and sharpen contrast, lateral inhibition occurs within the CNS (► Figure 4-5b). The most strongly activated signal pathway originating from the centre of the stimulus area inhibits the less excited pathways from the fringe areas. This occurs via inhibitory interneurons that pass laterally between ascending fibres serving neighbouring receptive fields. Blockage of further transmission in the weaker inputs increases the contrast between wanted and unwanted information so that the pencil point can be precisely localized. The extent of lateral inhibitory connections within sensory pathways varies for different modalities. Those with the most lateral inhibition—touch and vision—bring about the most accurate localization.

Mechanoreceptors

Mechanoreceptors come in different forms, but in essence are sensitive to pressure, stretch, vibration, acceleration, and sound. Some mechanoreceptors are discussed in other sections and chapters. (Section 4.6 of this chapter describes mechanoreceptors for sound, and Chapter 9 examines baroreceptors for pressure.) But here we focus on five types of mechanoreceptors that are important to the somatic sensation of touch: (1) Pacinian corpuscles, (2) Meissner's corpuscles, (3) Merkel's discs, (4) Ruffini corpuscles, and (5) free nerve endings. Touch (tactile) receptors are the most common in the body; they respond to various forms of physical contact such as pressure, vibration, stretch, texture, and caressing movements. They are found in the skin, deep tissues, muscle, joints, and organs; they are also difficult to study due to their small size.

Pacinian corpuscles are located in the skin and respond to touch and deep pressure, are useful in detecting moderately rough to rougher surfaces, and are very sensitive to vibration. Their distribution ranges from approximately 350 per finger to 800 in the palm. The Pacinian corpuscle is oval shaped, ~1 mm in length, and wrapped by a layer of connective tissue. They are classified as a phasic tactile mechanoreceptor. Their optimal

FIGURE 4-5 Lateral inhibition. (a) The receptor at the site of most intense stimulation is activated to the greatest extent. Surrounding receptors are also stimulated but to a lesser degree. (b) The most intensely activated receptor pathway halts transmission of impulses in the less intensely stimulated pathways through lateral inhibition. This process facilitates localization of the site of stimulation.

sensitivity is about 250 Hz, and this is the frequency range generated upon fingertips by textures made of very small features ($\sim 200 \mu\text{m}$). They respond to transient touches rather than sustained pressure, because they are rapidly adapting receptors. (The mechanism by which adaptation is accomplished varies for different receptors and has not been fully elucidated for all receptor types.)

Adaptation in a Pacinian corpuscle involves both mechanical and electrochemical components. The mechanical component depends on the physical properties of this receptor. The receptor ending consists of concentric layers of connective tissue (20–60 concentric lamellae), resembling layers of an onion wrapped around the peripheral terminal of a myelinated afferent neuron. When pressure is first applied to the Pacinian corpuscle, the underlying terminal responds with a receptor potential that reflects the intensity of the stimulus. As the stimulus continues, the pressure energy is dissipated because it causes the receptor layers to slip (just as the layers of an onion slip under pressure). Because this physical effect filters out the steady component of the applied pressure, the underlying neuronal ending no longer responds with a receptor potential and adaptation occurs.

Meissner's corpuscles are a phasic, tactile, myelinated mechanoreceptor, consisting of nerve endings located in the skin that are responsible for sensing light touch. They have a low threshold when sensing vibration ($<50 \text{ Hz}$), and they rapidly adapt. Their receptive field is about 3–5 mm. Structurally, they are encapsulated nerve endings surrounded by a connective tissue capsule. The corpuscle is 30–140 μm in length, 40–60 μm in diameter, and has a density of approximately 150 per cm^2 at the fingertip. They are distributed on various areas of the skin, but concentrated in areas sensitive to light touch such as the fingers, lips, and nipples.

Of all the mechanoreceptors, **Merkel's discs** are the most sensitive to low frequency vibrations (5–15 Hz), having a receptive field of about 2–3 mm. They are classified as a slow-adapting, type I myelinated mechanoreceptor that provides touch information. Merkel's discs are found in the superficial layers of the skin and mucosa. They are found clustered beneath the ridges of the fingertips that make up fingerprints. Merkel nerve endings are extremely sensitive to tissue displacement, and may respond to less than 1 μm of displacement. Merkel nerve endings are clustered into specialized epithelial structures called *touch domes* or *hair disks*. They are also located in the mammary glands.

Ruffini corpuscles are slow-adapting, myelinated nerve endings found in the deep layers of the skin (subcutaneous tissue) and joints. They are encapsulated, tied into the local collagen matrix, and respond to stretch (deformation) and torque. They register mechanical deformation within joints (sensitivity of 2 degrees), as well as continuous pressure.

Free nerve endings are found in the skin, around hair roots, in the eyes, and many other tissues. They may be myelinated or unmyelinated, and are the most abundant of the skin receptors. Free nerve endings specialize in detecting touch and pressure, but are also used for temperature and nociception (sensing pain). When you touch your eye while putting in your contact lens, or rub your eye to remove debris, the free nerve endings associated with the cornea make you aware of the pressure and

touch. Also, the sensations of tickling and itching are detected by free nerve endings, considered noxious stimuli—most commonly found in the superficial skin—and transmitted via unmyelinated slow fibres.

Having completed our discussion of receptor physiology associated with the somatic sense touch, we are now going to examine one important somatic sensation in greater detail—pain.

Check Your Understanding 4.1

2. Draw the response of a tonic receptor and of a phasic receptor to a stimulus of sustained strength.
3. Compare the receptive field size for a sensory neuron on your tongue and a sensory neuron on your back.

4.4 | Pain

Pain is an unpleasant sensation, associated with **nociceptor** stimulation (nociception is the perception of physiological pain) and is a measurable physiological event. “Pain” comes from the Latin *poena*, meaning punishment or penalty. Pain can also include nociception from both external, perceived events (e.g., seeing something) and internal, cognitive events (e.g., phantom limb pain; p. 147). Nociception is a critical component of the body’s defence system because it is part of a rapid-warning system that relays instructions to the CNS to initiate an efferent motor response, thereby triggering cognitive processes to reduce or remove the physical harm.

Stimulation of nociceptors

Unlike other somatosensory modalities, the sensation of pain is accompanied by motivated behavioural responses such as the withdrawal reflex, as well as emotional reactions such as crying. As well, the subjective perception of pain can be influenced by other past or present experiences—for example, heightened pain perception accompanying fear of the dentist.

CATEGORIES OF PAIN RECEPTORS

Nociceptors form late during neurogenesis, developing from neural crest stem cells, which are responsible for development of the peripheral nervous system. There are three categories

of nociceptors classified by modality. **Mechanical nociceptors** respond to mechanical damage, such as cutting, crushing, or pinching. **Thermal nociceptors** respond to temperature extremes, especially heat. **Chemical nociceptors** respond equally to many kinds of irritating chemicals released from damaged tissue. The nociceptor free nerve endings are found in skin and deep tissue, joints, muscle, and bone. Because of their value to survival, nociceptors do not adapt to sustained or repetitive stimulation.

A good example of nociception is the noxious response to heat (temperature). Since the discovery of the **capsaicin** (active ingredient in hot chili peppers) receptor (TRPV1), the mechanism for thermal pain transduction has been well documented. Thermal pain is detected via a channel-gated nociceptor. Six types of thermo-TRP receptors are known: Transient Receptor Potential Vanilloid (TRPV) 1, TRPV2, TRPV3, TRPV4, TRPM8, and TRPA1. TRPV1 and TRPV2 are sensitive to noxious heat and warmth, whereas TRPV3 and TRPV4 are sensitive to cool and cold, respectively. Still other transient receptor potential (TRP) receptors are undetermined.

 Nociceptors can be modulated by the presence of chemicals such as *prostaglandins*, which greatly enhance the receptor response to noxious stimuli. Prostaglandins are a special group of fatty acid derivatives that are cleaved from the lipid bilayer of the plasma membrane and act locally once released (p. 741). Tissue injury, among other things, can lead to the local release of prostaglandins. These chemicals act on the nociceptors’ peripheral endings to lower their activation threshold. Aspirin-like drugs inhibit the synthesis of prostaglandins, which accounts at least in part for the analgesic (pain-relieving) properties of these types of drugs. Other chemical substances that influence nociceptors are histamine, potassium, serotonin, and substance P (peptides). These chemicals also affect the inflammatory response associated with damaged tissue.

FAST AND SLOW AFFERENT PAIN FIBRES

Nerve impulses vary in conduction speed, and the conduction velocity is based on myelination and nerve fibre size. We judge and categorize pain as either **fast pain** or **slow pain**. Pain impulses from nociceptors are transmitted to the CNS via one of two types of afferent fibres, which range in size and conduction speed (■ Table 4-2): **A-delta (δ) fibres**, which are largest and fastest, and **C fibres**, which are smallest and slowest. Signals resulting from cold, warmth, and mechanical stimuli are

■ TABLE 4-2 Characteristics of Pain Nerve Fibres

Fibre Types	General Characteristics	Speed	Diameter	Stimuli	Description	Receptor Classification
Aδ	Small and myelinated	6–30 m/sec	1–5 µm	Fast pain, cold, warmth, mechanical	Sharp, stabbing, or acute	Free nerve ending
C Fibres	Small and unmyelinated	<1–2 m/sec	0.5–2 µm	Slow pain, heat, cold, mechanical	Burning, aching, throbbing	Free nerve ending

transmitted via fast myelinated A δ fibres at rates of 6–30 m/sec. Impulses carried via unmyelinated slow C fibres carry slow pain, heat, cold, and mechanical stimuli at a much slower rate of <1–2 m/sec.

Think about the last time you cut or burned your finger. You undoubtedly felt a sharp twinge of pain at first, with a more diffuse, disagreeable pain commencing shortly thereafter. Pain typically is perceived initially as a brief, sharp, prickling sensation that is easily localized; this is the fast pain pathway originating from specific mechanical or heat nociceptors. This feeling is followed by a dull, aching, poorly localized sensation that persists for a longer time and is more unpleasant; this is the **slow pain pathway**, which is activated by chemicals, especially **bradykinin**, a normally inactive substance that is activated by enzymes released into the ECF from damaged tissue. Bradykinin and related compounds not only provoke pain—presumably by stimulating the **polymodal nociceptors**—but also contribute to the inflammatory response to tissue injury (Chapter 11). Polymodal receptors are small-diameter receptors that respond to more than one type of noxious (painful) stimulus (e.g., heat or mechanical stimuli). The persistence of these chemicals might explain the long-lasting, aching pain that continues after removal of the mechanical or thermal stimulus that caused the tissue damage.

HIGHER-LEVEL PROCESSING OF PAIN INPUT

Multiple structures are involved in pain processing. The primary afferent pain fibres synapse with specific second-order interneurons in the dorsal horn of the spinal cord. In response to stimulus-induced action potentials, afferent pain fibres release neurotransmitters that influence these next neurons in line. The two best known of these pain neurotransmitters are *substance P* and *glutamate*. **Substance P** activates ascending pathways that transmit nociceptive signals to higher levels for further processing (► Figure 4-6a). Ascending pain pathways have different destinations in the *cortex*, the *thalamus*, and the *reticular formation*. Cortical somatosensory processing areas localize the pain, whereas other cortical areas participate in other conscious components of the pain experience, such as deliberation about the incident. In the absence of the cortex, pain can still be perceived, presumably at the level of the thalamus. The reticular formation increases the level of alertness associated with the noxious encounter. Interconnections from the thalamus and reticular formation to the hypothalamus and limbic system elicit the behavioural and emotional responses accompanying the painful experience. The limbic system appears to be especially important in perceiving the unpleasant aspects of pain.

Glutamate, the other neurotransmitter released from primary afferent pain terminals, is a major excitatory neurotransmitter (p. 77). Glutamate acts on two different types of plasma membrane receptors on the dorsal horn neurons, with two different outcomes (p. 130). First, binding of glutamate with its *AMPA receptors* leads to permeability changes that ultimately result in the generation of action potentials in the dorsal horn cell. These action potentials transmit the pain message to higher centres. Second, binding of glutamate with its *NMDA receptors* leads to calcium (Ca^{2+}) entry into the dorsal horn cell. This pathway is not involved in the transmission of pain messages. Instead, Ca^{2+} initiates second-messenger systems that make the dorsal horn

neuron more excitable than usual. This hyperexcitability contributes in part to the exaggerated sensitivity of an injured area to subsequent exposure to painful, or even normally nonpainful, stimuli, such as a light touch. Think about how exquisitely sensitive your sunburned skin is, even to clothing. Other mechanisms in addition to glutamate-induced hyperexcitability of the dorsal horn neurons also contribute to supersensitivity of an injured area. For example, responsiveness of the pain-sensing peripheral receptors can be boosted so that they react more vigorously to subsequent stimuli. This exaggerated sensitivity presumably serves a useful purpose by discouraging activities that could cause further damage or interfere with healing of the injured area. Usually this hypersensitivity resolves as the injury heals.

 **Chronic pain**, sometimes excruciating, occasionally occurs in the absence of tissue injury. In contrast to the pain accompanying peripheral injury, which serves as a normal protective mechanism to warn of impending or actual damage to the body, abnormal chronic pain states result from damage within the pain pathways in the peripheral nerves or the CNS. That is, pain is perceived because of abnormal signalling within the pain pathways in the absence of peripheral injury or typical painful stimuli. For example, strokes that damage ascending pathways can lead to an abnormal, persistent sensation of pain.

Clinical Connections

This abnormal chronic pain is sometimes categorized as **neuropathic pain**, which is what someone with diabetic peripheral neuropathy can experience. At night, Deborah was experiencing sharp pains in her toes. Her diabetes had led to injury of A δ fibres that resulted in the inappropriate signalling of pain to the CNS. As well, this could be related to why she was experiencing pain when standing. Although pain receptors may not have been directly activated by standing, because they were injured, they may have misinterpreted the pressures on the lower extremities during standing and initiated pain signalling.

The brain's built-in analgesic system

In addition to the chain of neurons connecting peripheral nociceptors with higher CNS structures for pain perception, the CNS contains a built-in pain-suppressing or **analgesic system** that suppresses transmission in the pain pathways as they enter the spinal cord. Two regions are known to be a part of this descending analgesic pathway. Electrical stimulation of the *periaqueductal grey matter* (grey matter surrounding the cerebral aqueduct, a narrow canal that connects the third and fourth ventricular cavities) results in profound analgesia, as does stimulation of the *reticular formation* within the brain stem. This analgesic system suppresses pain by blocking the release of substance P from afferent pain-fibre terminals (► Figure 4-6b).

The analgesic system depends on the presence of **opiate receptors**. We have known for many years of the effect of morphine. Since the discovery of morphine as an analgesic, scientists began the search for endogenous opiates (that act like morphine) that bind these receptors and dull pain. They found that endorphins, enkephalins, and dynorphins were a part of the body's natural

FIGURE 4-6 Substance P pain pathway and analgesic pathway. (a) When activated by a noxious stimulus, some afferent pain pathways release substance P, which activates ascending pain pathways that provide various brain regions with input for processing different aspects of the painful experience. (b) Endogenous opiates released from descending analgesic (pain-relieving) pathways bind with opiate receptors at the synaptic knob of the afferent pain fibre. This binding inhibits the release of substance P, thereby blocking transmission of pain impulses along the ascending pain pathways.

Acupuncture: Is It for Real?

4

IT SOUNDS LIKE SCIENCE FICTION. How can a needle inserted in the hand relieve a toothache? Acupuncture analgesia (AA), the technique of relieving pain by inserting and manipulating threadlike needles at key points, has been practised in China for more than 2000 years but is relatively new to Western medicine.

Brief History

Traditional Chinese teaching holds that disease can occur when the normal patterns of flow of healthful energy (called *Qi*; pronounced “chee”) just under the skin become disrupted, and acupuncture is able to correct this imbalance and restore health. Many Western scientists have been skeptical because, until recently, the phenomenon could not be explained on the basis of any known, logical, physiological principles, although a tremendous body of anecdotal evidence in support of the effectiveness of AA existed in China. From the point of view of Western medicine, the success of acupuncture was considered a placebo effect. The term *placebo effect* refers to a

chemical or technique that brings about a desired response through the power of suggestion or distraction rather than through any direct action.

Because the Chinese accepted anecdotal evidence for the success of AA, this phenomenon did not come under close scientific scrutiny until European and American scientists started studying it in the last several decades. As a result, an impressive body of rigorous scientific investigation supports the contention that AA works based on a physiological rather than a placebo/psychological effect. In controlled clinical studies, 55–85 percent of patients were helped by AA. Pain relief was reported by only 30–35 percent of placebo controls (people who thought they were receiving proper AA treatment, but in whom needles were inserted in the wrong places or not deep enough). Furthermore, its mechanisms of action have become apparent. Indeed, more is known about the underlying physiological mechanisms of AA than about those of many conventional medical techniques, such as gas anesthesia.

analgesic system. These endogenous opiates serve as analgesic neurotransmitters; they are released from the descending analgesic pathway and bind with opiate receptors on the afferent pain-fibre terminal. This binding suppresses the release of substance P via presynaptic inhibition, thereby blocking further transmission of the pain signal (p. 81). Morphine binds to these same opiate receptors, which accounts for its analgesic properties.

It is not clear how this natural pain-suppressing mechanism is normally activated. Factors known to modulate pain include exercise, stress, and acupuncture. Researchers believe that endorphins are released during prolonged exercise and presumably produce the “runner’s high.” Some types of stress also induce analgesia. It is sometimes disadvantageous for a stressed organism to display the normal reaction to pain. For example, when two male lions are fighting for dominance of the group, withdrawing, escaping, or resting when injured would mean certain defeat. For an examination of how acupuncture relieves pain, see Concepts, Challenges, and Controversies.

We have now completed our coverage of somatic sensations, which included touch, temperature, and pain. As you are now aware, somatic sensation is detected by various types of widely distributed receptors that provide information about the body’s interactions with the environment. In contrast, each of the special senses has highly localized, extensively specialized receptors that respond to unique environmental stimuli. The special senses include *vision*, *hearing*, *taste*, *smell*, and *equilibrium* to which we now turn our attention, starting with vision.

Check Your Understanding 4.2

1. Compare and contrast the classes of pain receptors
2. Compare the type of pain signals transmitted via A-delta fibres and C fibres.
3. Describe the role of endogenous opiates in the body’s natural analgesic system.

4.5 | Eye: Vision

For **vision**, the eyes capture the patterns of illumination in the environment as an “optical picture” on a layer of light-sensitive cells, the *retina*. This coded image on the retina is transmitted through a series of progressively more complex steps of visual processing until it is finally perceived as a visual likeness of the original image. Before considering the steps involved in the process of vision, we first examine how the eyes are protected from injury.

Protective mechanisms and eye injuries

Several mechanisms help protect the eyes from injury. The bony socket in which the eye is positioned shelters the eyeball, except for its most anterior portion. The **eyelids** act like shutters to protect the front of the eye from environmental insults. They close reflexly to cover the eye under threatening circumstances,

Mechanism of Action

An overwhelming body of evidence supports the *acupuncture endorphin hypothesis* as the primary mechanism of AA's action. According to this hypothesis, acupuncture needles activate specific afferent nerve fibres, which send impulses to the central nervous system. Here, the incoming impulses activate three centres (a spinal cord centre, a mid-brain centre, and a hormonal centre—the anterior pituitary unit of the hypothalamus) to cause analgesia. Researchers have shown that all three centres block pain transmission by means of endorphins and closely related compounds. Several other neurotransmitters, such as serotonin and norepinephrine, as well as cortisol, the major hormone released during stress, are implicated as well. (Pain relief in placebo controls is believed to occur as a result of placebo responders subconsciously activating their own built-in analgesic system.)

Acupuncture in Canada

In Canada, AA has not been used in mainstream medicine, even by physicians who have been convinced by scientific evidence that the

technique is valid. AA methodology has traditionally not been taught in Canadian medical colleges, and the techniques take time to learn. Also, AA is much more time consuming than the use of drugs. Western physicians who have been trained to use drugs to solve most pain problems are generally reluctant to give up their known methods for an unfamiliar, time-consuming technique. However, acupuncture is gaining favour as an alternative treatment for relief of chronic pain, especially because analgesic drugs can have troublesome side effects. After decades of being spurned by most of the Canadian medical community, acupuncture started gaining respectability after the publication of scientific research. The research has suggested that acupuncture is effective as an alternative or adjunct to conventional treatment for many kinds of pain and nausea. Now that acupuncture has gained acceptance, some medical insurers now pay for this scientifically legitimate treatment, and some of the nation's medical schools have incorporated the technique into their curricula. There are now many accredited acupuncture schools for nonphysicians, and thousands of accredited acupuncturists.

such as rapidly approaching objects, dazzling light, and instances when the exposed surface of the eye or eyelashes are touched. Frequent, spontaneous blinking of the eyelids helps disperse the lubricating, cleansing, bactericidal (germ-killing) **tears**. Tears are produced continuously by the **lacrimal gland** in the upper lateral corner under the eyelid. This eye-washing fluid flows across the anterior surface of the eye, drains into tiny canals in the corner of each eye (► Figure 4-7a), and empties into the back of the nasal passageway. This drainage system cannot handle the profuse tear production during crying, so the tears overflow from the eyes. The eyes are also equipped with protective **eyelashes**, which trap fine, airborne debris, such as dust, before it can fall into the eye.

The eye: A fluid-filled sphere

Each **eye** is a spherical, fluid-filled structure enclosed by three layers. From outermost to innermost, these are (1) the **sclera/cornea**; (2) the **choroid/ciliary body/iris**; and (3) the **retina** (Figure 4-7b). Most of the eyeball is covered by a tough outer layer of connective tissue, the **sclera**, which forms the visible white part of the eye (Figure 4-7a). Anteriorly, the outer layer consists of the transparent **cornea**, through which light rays pass into the interior of the eye. The middle layer underneath the sclera is the **choroid**, which contains many blood vessels that nourish the retina. The choroid layer becomes specialized anteriorly to form the **ciliary body** and **iris**, which will be described shortly. The innermost coat under the choroid is the **retina**, which consists of an outer layer and an inner nervous-tissue

layer. The latter contains the **rods** and **cones**, the photoreceptors that convert light energy into nerve impulses. The choroid and the outer layer of the retina are highly pigmented to prevent reflection, or scattering, of light within the eye.

The interior of the eye consists of two fluid-filled cavities, separated by an elliptical **lens**, all of which are transparent to permit light to pass through the eye from the cornea to the retina. The larger cavity between the lens and retina contains a semifluid, jelly-like substance, the **vitreous humour**. The vitreous humour is important in maintaining the spherical shape of the eyeball. The anterior cavity between the cornea and lens contains a clear, watery fluid, the **aqueous humour**. The aqueous humour carries nutrients for the cornea and lens, both of which lack a blood supply. Blood vessels in these structures would impede the passage of light to the photoreceptors.

Aqueous humour is produced at a rate of about 5 mL/day by a capillary network within the **ciliary body**, a specialized anterior derivative of the choroid layer. This fluid drains into a canal at the edge of the cornea and eventually enters the blood (► Figure 4-8).

If aqueous humour is not drained as rapidly as it forms (e.g., because of a blockage in the drainage canal), the excess accumulates in the anterior cavity, causing the pressure to rise within the eye. This condition is known as **glaucoma**. The excess aqueous humour pushes the lens backward into the vitreous humour, which in turn is pushed against the inner neural layer of the retina. This compression causes retinal and optic nerve damage that can lead to blindness if the condition is not treated.

© 2016 Cengage

► **FIGURE 4-7** Structure of the eye. (a) External front view. (b) Internal sagittal view

The iris

Not all the light passing through the cornea reaches the light-sensitive photoreceptors. This is due to the iris, a thin, pigmented smooth muscle that forms a visible ringlike structure within the aqueous humour (see ► Figure 4-7a and ► 4-7b). The pigment in the iris is responsible for eye colour. The varied flecks, lines, and other nuances of the iris are unique for each individual, making the iris the basis of the latest identification technology. Recognition of iris patterns by a video camera that captures iris images and translates the landmarks into a computerized code is more foolproof than fingerprinting or even DNA testing.

The round opening in the centre of the iris through which light enters the interior portions of the eye is the **pupil**. The size of this opening can be adjusted by variable contraction of the iris muscles to admit more or less light as needed, much as the diaphragm controls the amount of light entering a camera. The iris contains two sets of smooth muscle networks, one *circular* (the muscle fibres run in a ringlike fashion within the iris) and the other *radial* (the fibres project outward from the pupillary margin like bicycle spokes) (► Figure 4-9). Because muscle fibres

► **FIGURE 4-8** Formation and drainage of aqueous humour. Aqueous humour is formed by a capillary network in the ciliary body, then drains into the canal of Schlemm, and eventually enters the blood.

➤ **FIGURE 4-9** Control of pupillary size

shorten when they contract, the pupil gets smaller when the **circular (constrictor) muscle** contracts and forms a smaller ring. This reflex pupillary constriction occurs in bright light to decrease the amount of light entering the eye. When the **radial (dilator) muscle** shortens, the size of the pupil increases. Such pupillary dilation occurs in dim light to allow the entrance of more light. Iris muscles are controlled by the autonomic nervous system (ANS). Parasympathetic nerve fibres innervate the circular muscle (causing pupillary constriction), whereas sympathetic fibres supply the radial muscle (causing pupillary dilation).

Properties of light waves

Light is a form of electromagnetic radiation composed of particle-like individual packets of energy called **photons** that travel in wavelike fashion. The distance between two wave peaks is known as the **wavelength** (➤ Figure 4-10). The wavelengths in the electromagnetic spectrum range from 10^{-14} m (quadrillionths of a metre, as in the extremely short cosmic rays) to 10^4 m (10 km, as in long radio waves) (➤ Figure 4-11). The visible light range is between 400 and 700 nm (a billionth of a metre), a small portion of the total spectrum. This range, however, is sufficient to allow us to perceive different colour sensations, since different wavelengths correspond to different colours. The shorter visible wavelengths are sensed as violet and blue; the longer wavelengths are interpreted as orange and red.

In addition to having variable wavelengths, light energy also varies in intensity; that is, the amplitude, or height, of the wave (➤ Figure 4-10). Dimming a bright red light does not change its colour; it just becomes less intense or less bright.

Light waves *diverge* (radiate outward) in all directions from every point of a light source. The forward movement of a light wave in a particular direction is known as a **light ray**.

Divergent light rays reaching the eye must be bent inward to be focused back into a point (the **focal point**) on the light-sensitive retina to provide an accurate image of the light source.

Light travels faster through air than through other transparent media, such as water and glass. When a light ray enters a medium of greater density, it is slowed down (the converse is also true). The course of direction of the ray changes if it strikes the surface of the new medium at any angle other than perpendicular. The bending of a light ray is known as **refraction**. With a curved surface, such as a lens, the greater the curvature is, the greater the degree of bending and the stronger the lens. When a light ray strikes the curved surface of any object of greater density, the direction of refraction depends on the angle of the curvature (➤ Figure 4-12). A **convex** surface curves outward (like the outer surface of a ball), whereas a **concave** surface curves inward (like a cave). Convex surfaces

➤ **FIGURE 4-10** Properties of an electromagnetic wave. A *wavelength* is the distance between two wave peaks. The *intensity* is the amplitude of the wave.

converge light rays, bringing them closer together. Concave surfaces diverge light rays (spread them farther apart).

The eye's refractive structures

The cornea and lens are the structures most important to the eye's refractive ability. The first structure, the curved corneal surface, contributes most extensively to the eye's total refractive ability because the difference in density at the air–cornea interface is much greater than the differences in density between the lens and the fluids surrounding it. In **astigmatism** the curvature of the cornea is uneven, so light rays are unequally refracted. The refractive ability of a person's cornea remains constant, because the curvature of the cornea never changes. In contrast, the refractive ability of the lens can be adjusted by changing its curvature as needed for near or far vision. Rays from light sources more than six metres away are considered parallel by the time they reach the eye. By contrast, light rays originating from near objects are still diverging when they reach the eye. For a given refractive ability of the eye, divergent rays from a near source of light are brought to a focal point at a greater distance from the lens than parallel rays from a far source of light (► Figure 4-13a and ► 4-13b). However, in a particular eye the distance between the lens and the retina always remains the same. Therefore, a greater distance beyond the lens is not available for bringing near objects into focus. Yet for clear vision, the refractive structures of the eye must bring both near and far light sources into focus on the retina (i.e., in the same distance), a stronger lens must be used for the near source (► Figure 4-13c). Let's see how the strength of the lens can be adjusted as needed.

► **FIGURE 4-12 Refraction by convex and concave lenses.** (a) A lens with a convex surface, which converges the rays (brings them closer together). (b) A lens with a concave surface, which diverges the rays (spreads them farther apart)

► **FIGURE 4-13 Focusing of distant and near sources of light.** (a) The rays from a distant (far) light source (more than six metres from the eye) are parallel by the time the rays reach the eye. (b) The rays from a near light source (less than six metres from the eye) are still diverging when they reach the eye. A longer distance is required for a lens of a given strength to bend the diverging rays from a near light source into focus compared with the parallel rays from a distant light source. (c) To focus on both distant and near light sources in the same distance (i.e., the distance between the lens and retina), a stronger lens must be used for the near source.

Accommodation

The ability to adjust the strength of the lens is known as **accommodation**. The strength of the lens depends on its shape, which in turn is regulated by the ciliary muscle.

The **ciliary muscle** is part of the ciliary body, an anterior specialization of the choroid layer. The ciliary body has two major components: the ciliary muscle and the capillary network that produces aqueous humour (see Figure 4-8). The ciliary muscle is a circular ring of smooth muscle attached to the lens by **suspensory ligaments** (► Figure 4-14a and ► 4-14b).

When the ciliary muscle is relaxed, the suspensory ligaments are taut, and they pull the lens into a flattened, weakly refractive shape (► Figure 4-14c). As the muscle contracts, its circumference decreases, slackening the tension in the suspensory ligaments (► Figure 4-14d). When the suspensory ligaments subject the lens to less tension, it becomes more spherical, because of its inherent elasticity. The greater curvature of the more rounded lens increases its refractive abilities, further bending light rays. In the normal eye, the ciliary muscle is relaxed, and the lens is flat for far vision, but the muscle contracts to let the lens become more convex and

stronger for near vision. The ciliary muscle is controlled by the ANS, with sympathetic stimulation causing its relaxation and parasympathetic stimulation causing its contraction.

Clinical Note The lens is made up of about 1000 layers of cells that destroy their nucleus and organelles during development, so the cells are perfectly transparent. Lacking DNA and protein-synthesizing machinery, mature lens cells cannot regenerate or repair themselves. Cells in the centre of the lens are in double jeopardy. Not only are they oldest, but also they are farthest away from the aqueous humour, the lens's nutrient source. With advancing age, these nonrenewable central cells die and become stiff. With loss of elasticity, the lens can no longer assume the spherical shape required to accommodate for near vision. This age-related reduction in accommodative ability, **presbyopia**, affects most people by middle age (45–50), requiring them to resort to corrective lenses for near vision (reading).

The elastic fibres in the lens are normally transparent. These fibres occasionally become opaque so that light rays cannot pass through—a condition known as a **cataract**. The defective lens can usually be surgically removed and vision restored by an implanted artificial lens or by compensating eyeglasses.

Other common vision disorders are *nearsightedness* (*myopia*) and *farsightedness* (*hyperopia*). In a normal eye (**emmetropia**) (► Figure 4-15a), a far light source is focused on the retina without accommodation, whereas the strength of the lens is increased by accommodation to bring a near source into focus. In **myopia** (► Figure 4-15b1), because the eyeball is too long or the lens is too strong, a near light source is brought into focus on the retina without accommodation (even though accommodation is normally used for near vision), whereas a far light source is focused in front of the retina and is blurry. Thus, a myopic individual has better near vision than far vision, a condition that can be corrected by a concave lens (► Figure 4-15b2). With **hyperopia** (► Figure 4-15c1), either the eyeball is too short or the lens is too weak. Far objects are focused on the retina only with accommodation, whereas near objects are focused behind the retina even with accommodation and, accordingly, are blurry. Thus, a hyperopic individual has better far vision than near vision, a condition that can be corrected by a convex lens (► Figure 4-15c2). Instead of using corrective eyeglasses or contact lenses, many people are now opting to compensate for refractive errors with laser eye surgery (such as LASIK) to permanently change the shape of the cornea.

The retinal layers

The primary responsibility of the eye is to focus light rays on to the rods and cones, which transform the light energy into electrical signals that are sent to the CNS.

The receptor-containing portion of the retina is actually an extension of the CNS, not a separate peripheral organ. During embryonic development, the retinal cells “back out” of the nervous system, so the retinal layers, surprisingly, are facing backward! The neural portion of the retina consists of three layers of excitable cells (► Figure 4-16): (1) the outermost layer (closest to the choroid) containing the rods and cones, whose light-sensitive ends face the choroid (away from the incoming light); (2) a middle layer of **bipolar cells**; and (3) an inner layer of **ganglion cells**. Axons of

► **FIGURE 4-14 Mechanism of accommodation.** (a) Schematic representation of suspensory ligaments extending from the ciliary muscle to the outer edge of the lens. (b) Scanning electron micrograph showing the suspensory ligaments attached to the lens. (c) When the ciliary muscle is relaxed, the suspensory ligaments are taut, putting tension on the lens so that it is flat and weak. (d) When the ciliary muscle is contracted, the suspensory ligaments become slack, reducing the tension on the lens. The lens can then assume a stronger, rounder shape because of its elasticity.

the ganglion cells join to form the **optic nerve**, which leaves the retina slightly off-centre. The point on the retina at which the optic nerve leaves and through which blood vessels pass is the **optic disc** (see Figure 4-7b). This region is often called the **blind spot**; no image can be detected in this area because it has no rods and cones (► Figure 4-17). We are normally not aware of the blind spot, because central processing somehow “fills in” the missing spot. You can discover the existence of your own blind spot by a simple demonstration (► Figure 4-18).

Light must pass through the ganglion and bipolar layers before reaching the photoreceptors in all areas of the retina except the fovea. In the **fovea**, which is a pinhead-sized depression located in the exact centre of the retina, the bipolar and ganglion cell layers are pulled aside so that light strikes the photoreceptors directly (see Figure 4-7b). This feature, coupled with the fact that

only cones (which have greater acuity or discriminative ability than the rods) are found here, makes the fovea the point of most distinct vision. In fact, the fovea has the greatest concentration of cones in the retina. Thus, we turn our eyes so that the image of the object at which we are looking is focused on the fovea. The area immediately surrounding the fovea, the **macula lutea**, also has a high concentration of cones and fairly high acuity (► Figure 4-17). Macular acuity, however, is less than that of the fovea, because of the overlying ganglion and bipolar cells in the macula.

Clinical Note **Macular degeneration** is the leading cause of blindness in the western hemisphere. This condition is characterized by loss of photoreceptors in the macula lutea in association with advancing age. Its victims have “doughnut” vision. They suffer a loss in the middle of their visual field, which normally has the highest acuity, and are left with only the less distinct peripheral vision.

► **FIGURE 4-16 Retinal layers.** The retinal visual pathway extends from the photoreceptor cells (rods and cones, whose light-sensitive ends face the choroid away from the incoming light) to the bipolar cells, and then to the ganglion cells. The horizontal and amacrine cells act locally for retinal processing of visual input.

Photoreceptors

A photoreceptor is a specialized type of neuron in the eye's retina. The two types of photoreceptor cells are rods and cones. Cones are adapted to detect colours and work well in bright light. Rods are

more sensitive but do not detect colour well; they are adapted for low light. The photoreceptor consists of three parts (► Figure 4-19a):

1. An *outer segment*, which lies closest to the eye's exterior, facing the choroid. It detects the light stimulus.
2. An *inner segment*, which lies in the middle of the photoreceptor's length. It contains the metabolic machinery of the cell.
3. A *synaptic terminal*, which lies closest to the eye's interior, facing the bipolar cells. It transmits the signal generated in the photoreceptor on light stimulation to these next cells in the visual pathway.

► **FIGURE 4-17 View of the retina seen through an ophthalmoscope.** With an ophthalmoscope, a lighted viewing instrument, it is possible to view the optic disc (blind spot) and macula lutea within the retina at the rear of the eye.

► **FIGURE 4-18 Demonstration of the blind spot.** Find the blind spot in your left eye by closing your right eye and holding the book about 10 cm from your face. While focusing on the cross, gradually move the book away from you until the circle vanishes from view. At this time, the image of the circle is striking the blind spot of your left eye. You can similarly locate the blind spot in your right eye by closing your left eye and focusing on the circle. The cross will disappear when its image strikes the blind spot of your right eye.

The outer segment, which is rod shaped in rods and cone shaped in cones (► Figure 4-19a), consists of stacked, flattened, membranous discs containing an abundance of light-sensitive *photopigment* molecules. Each retina has about 150 million photoreceptors, and more than a billion photopigment molecules may be packed into the outer segment of each photoreceptor.

Photopigments undergo chemical alterations when activated by light. Through a series of steps, this light-induced change and subsequent activation of the photopigment bring about a receptor potential that ultimately leads to the generation of action potentials, which transmit this information to the brain for visual processing. A photopigment consists of two components: **opsin**, a protein that is an integral part of the disc membrane; and **retinene**, a derivative of vitamin A that is bound within the interior of the opsin molecule (► Figure 4-19b). Retinene is the light-absorbing part of the photopigment.

There are four different photopigments: one in the rods and one in each of three types of cones. These four photopigments differentially absorb various wavelengths of light. **Rhodopsin**, the rod photopigment, absorbs all visible wavelengths. Using visual input from the rods, the brain cannot discriminate between various wavelengths in the visible spectrum. Therefore, rods provide vision only in shades of grey by detecting different intensities, not different colours. The photopigments in the three types of cones—**red, green, and blue cones**—respond selectively to various wavelengths of light, making colour vision possible.

Phototransduction, the process of converting light stimuli into electrical signals, is basically the same for all photoreceptors, but the mechanism is contrary to the usual means by which receptors respond to their adequate stimulus. Specifically, receptors typically *depolarize* when stimulated, whereas photoreceptors *hyperpolarize* on light absorption. Let's first examine the status of the photoreceptors in the dark, and then consider what happens when they are exposed to light.

PHOTORECEPTOR ACTIVITY IN THE DARK

The plasma membrane of a photoreceptor's outer segment contains chemically gated Na^+ channels. Unlike other chemically gated channels that respond to extracellular chemical messengers, these channels respond to an internal second messenger: **cyclic GMP (cGMP)** (cyclic guanosine monophosphate). The binding of cGMP to these Na^+ channels keeps them open. In the absence of light, the concentration of cGMP is high (Figure 4-20a). Therefore, the Na^+ channels of a photoreceptor, unlike most receptors, are open in the absence of stimulation—that is, in the dark. The resultant passive, inward Na^+ leak depolarizes the photoreceptor. The passive spread of this depolarization from the outer segment (where the Na^+ channels are located) to the synaptic terminal (where the photoreceptor's neurotransmitter is stored) keeps the synaptic terminal's voltage-gated Ca^{2+} channels open. Ca^{2+} entry triggers the release of neurotransmitter from the synaptic terminal while in the dark.

PHOTORECEPTOR ACTIVITY IN THE LIGHT

On exposure to light, the concentration of cGMP is decreased through a series of biochemical steps triggered by photopigment activation (► Figure 4-20b). Retinene changes shape when

it absorbs light (see ► Figure 4-19b). This change in conformation activates the photopigment. Rod and cone cells contain a G protein (p. 217) called **transducin**. The activated photopigment activates transducin, which in turn activates the intracellular enzyme phosphodiesterase. This enzyme degrades cGMP, thus decreasing the concentration of this second messenger in the photoreceptor. During the light excitation process, the reduction in cGMP permits the chemically gated Na^+ channels to close. This channel closure stops the depolarizing Na^+ leak and causes membrane hyperpolarization. This hyperpolarization, which is the receptor potential, passively spreads from the outer segment to the synaptic terminal of the photoreceptor. Here the potential changes lead to closure of the voltage-gated Ca^{2+} channels and a subsequent reduction in neurotransmitter release from the synaptic terminal. Thus, photoreceptors are *inhibited by their adequate stimulus* (hyperpolarized by light) and *excited in the absence of stimulation* (depolarized by darkness). The hyperpolarizing potential and subsequent decrease in neurotransmitter release are graded according to the intensity of light. The brighter the light is, the greater the hyperpolarizing response and the greater the reduction in neurotransmitter release.

FURTHER RETINAL PROCESSING OF LIGHT INPUT

How does the retina signal the brain about light stimulation through such an inhibitory response? The photoreceptors synapse with bipolar cells. These cells, in turn, terminate on the ganglion cells, whose axons form the optic nerve for transmission of signals to the brain. The neurotransmitter released from the photoreceptors' synaptic terminal has an *inhibitory* action on the bipolar cells. The reduction in neurotransmitter release that accompanies light-induced receptor hyperpolarization decreases this inhibitory action on the bipolar cells. Removal of inhibition has the same effect as direct excitation of the bipolar cells. The greater the illumination is on the receptor cells, the greater the removal of inhibition from the bipolar cells and the greater the excitation of the visual pathway to the brain.

Bipolar cells, similar to the photoreceptors, display graded potentials and do not conduct action potentials. This is in contrast to the ganglion cells, the first neurons in the chain, which propagate the visual message over long distances to the brain through the generation of action potentials.

The altered photopigments are restored to their original conformation in the dark by enzyme-mediated mechanisms (see ► Figure 4-19b). Subsequently, the membrane potential and rate of neurotransmitter release of the photoreceptor are returned to their basal state, and no further action potentials are transmitted to the visual cortex (► Figure 4-20a).

Clinical Note Researchers are currently working on an ambitious and still highly speculative microelectronic chip that would serve as a partial substitute retina. Their hope is that the device will be able to restore at least some sight in people who are blinded by loss of photoreceptor cells, but whose ganglion cells and optic pathways remain healthy. For example, if the research is successful, the chip could benefit people with macular degeneration. The envisioned “vision chip” would bypass the photoreceptor step altogether: images received by means of a camera mounted on eyeglasses would be translated by the chip

into electrical signals detectable by the ganglion cells and transmitted on for further optical processing. Another promising avenue under investigation for halting or even reversing the loss of sight in degenerative eye diseases involves regenerating the retina through use of fetal retinal cell transplants.

Properties of rods and cones

The retina contains more than 30 times as many rods as cones (100 million rods compared with 3 million cones per eye). Cones are most abundant in the macula lutea in the centre of the retina. From this point outward, the concentration of cones decreases and the concentration of rods increases. Rods are most abundant in the periphery. We have examined the similar way in which phototransduction takes place in rods and cones. Now we focus on the differences between these photoreceptors. You already know that rods provide vision only in shades of grey, whereas cones provide colour vision. The capabilities of the rods and cones also differ in other respects because of a difference in the “wiring patterns” between these photoreceptor types and other retinal neuronal layers (■ Table 4-3). Cones have low sensitivity to light, being “turned on” only by bright daylight, but they have high acuity (sharpness; ability to distinguish between two nearby points). Thus, cones provide sharp vision with high resolution for fine detail. Humans use cones for day vision, which is in colour and distinct. Rods, in contrast, have low acuity but high sensitivity, so they respond to the dim light of night. You can see at night with your rods but at the expense of colour and distinctness. Let us see how wiring patterns influence sensitivity and acuity.

There is little convergence of neurons in the retinal pathways for cone output (p. 83). Each cone generally has a private line connecting it to a particular ganglion cell. In contrast, there is much convergence in rod pathways. Output from more than 100 rods may converge via bipolar cells onto a single ganglion cell.

■ TABLE 4-3 Properties of Rod Vision and Cone Vision

Rods	Cones
100 million per retina	3 million per retina
Vision in shades of grey	Colour vision
High sensitivity	Low sensitivity
Low acuity	High acuity
Night vision	Day vision
Much convergence in retinal pathways	Little convergence in retinal pathways
More numerous in periphery	Concentrated in fovea and macula lutea

Before a ganglion cell can generate an action potential, the cell must be brought to threshold through the influence of the graded potentials in the receptors to which it is wired. Because a single-cone ganglion cell is influenced by only one cone, only bright daylight is intense enough to induce a sufficient receptor potential in the cone to ultimately bring the ganglion cell to threshold. The abundant convergence in the rod visual pathways, in contrast, offers good opportunities for summation of subthreshold events in a rod ganglion cell (p. 78–79). Whereas a small receptor potential induced by dim light in a single cone would not be sufficient to bring its ganglion cell to threshold, similar small receptor potentials induced by the same dim light in multiple rods converging on a single ganglion cell would have an additive effect to bring the rod ganglion cell to threshold. Because rods can bring about action potentials in response to small amounts of light, they are much more sensitive than cones. However, because cones have private lines into the optic nerve, each cone transmits information about an extremely small receptive field on the retinal surface. Cones are thus able to provide highly detailed vision at the expense of sensitivity. With rod vision, acuity is sacrificed for sensitivity. Because many rods share a single ganglion cell, once an action potential is initiated, it is impossible to discern which of the multiple rod inputs were activated to bring the ganglion cell to threshold. Objects appear fuzzy when rod vision is used, because of this poor ability to distinguish between two nearby points.

Sensitivity of the eyes to dark and light

The eyes’ sensitivity to light depends on the amount of light-responsive photopigment present in the rods and cones. When you go from bright sunlight into darkened surroundings, you cannot see anything at first, but gradually you begin to distinguish objects as a result of the process of **dark adaptation**. Breakdown of photopigments during exposure to sunlight tremendously decreases photoreceptor sensitivity. For example, a reduction in the content of inactivated rhodopsin by only 0.6 percent from its maximum value decreases rod sensitivity approximately 3000 times. In the dark, the photopigments broken down during light exposure are gradually regenerated. As a result, the sensitivity of your eyes gradually increases so you can begin to see in the darkened surroundings. However, only the highly sensitive, rejuvenated rods are “turned on” by the dim light.

Conversely, when you move from the dark to the light (e.g., leaving a movie theatre and entering the bright sunlight), at first your eyes are very sensitive to the dazzling light. With little contrast between lighter and darker parts, the entire image appears bleached. As some of the photopigments are rapidly broken down by the intense light, the sensitivity of the eyes decreases and normal contrasts can once again be detected, a process known as **light adaptation**. The rods are so sensitive to light that enough rhodopsin is broken down in bright light to essentially “burn out” the rods; that is, after the rod photopigments have already been broken down by the bright light, they no longer can respond to the light. Furthermore, a central neural adaptive mechanism switches the eyes from the rod system to the cone system on exposure to bright light. Therefore, only the less sensitive cones are used for day vision.

Clinical Note Researchers estimate that our eyes' sensitivity can change as much as 1 million times as they adjust to various levels of illumination through dark and light adaptation. These adaptive measures are also enhanced by pupillary reflexes that adjust the amount of available light permitted to enter the eye.

Because retinene, one of the photopigment components, is a derivative of vitamin A, adequate amounts of this nutrient must be available for the ongoing resynthesis of photopigments. **Night blindness** occurs as a result of dietary deficiencies of vitamin A. Although photopigment concentrations in both rods and cones are reduced in this condition, there is still enough cone photopigment to respond to the intense stimulation of bright light, except in the most severe cases. However, even modest reductions in rhodopsin content can decrease the sensitivity of rods so much that they cannot respond to dim light. In this condition, a person can see in the day by using cones but cannot see at night because the rods are no longer functional. So carrots are “good for your eyes” because they are rich in vitamin A.

Colour vision

Vision depends on stimulation of retinal photoreceptors by light. Certain objects in the environment, such as the sun, fire, and light bulbs, emit light. But how do you see such objects as chairs, trees, and people, which do not emit light? The pigments in various objects selectively absorb particular wavelengths of light transmitted to them from light-emitting sources, and the unabsorbed wavelengths are reflected from the objects' surfaces. These reflected light rays enable you to see the objects. An object perceived as blue absorbs the longer red and green wavelengths of light and reflects the shorter blue wavelengths, which can be absorbed by the photopigment in the eyes' blue cones, thereby activating them.

Each cone type is most effectively activated by a particular wavelength of light in the range of colour indicated by its name—blue, green, or red. However, cones also respond in varying degrees to other wavelengths (▶ Figure 4-21). **Colour vision**, the perception of the many colours of the world, depends on the three cone types' various *ratios of stimulation* in response to different wavelengths. A wavelength perceived as blue does not stimulate red or green cones at all but excites blue cones maximally (the percentage of maximal stimulation for red, green, and blue cones, respectively, is 0:0:100). The sensation of yellow, in comparison, arises from a stimulation ratio of 83:83:0—that is, red and green cones are stimulated 83 percent of maximum, and blue cones are not excited at all. The ratio for green is 31:67:36, and so on, with various combinations giving rise to the sensation of all the different colours. White is a mixture of all wavelengths of light, whereas black is the absence of light.

The extent to which each of the cone types is excited is coded and transmitted in separate, parallel pathways to the brain. A distinct colour vision centre in the primary visual cortex combines and processes these inputs to generate the perception of colour, taking into account the object in comparison with its background. The concept of colour is therefore in the mind of the beholder. Most of us agree on what colour we see because we have the same types of cones and use similar neural pathways

for comparing their output. Occasionally, however, individuals lack a particular cone type, so their colour vision is a product of the differential sensitivity of only two types of cones—a condition known as **colour blindness**. Not only do those with colour blindness perceive certain colours differently, they also cannot distinguish as many varieties of colours (▶ Figure 4-22). For example, people with certain defects in colour perception cannot distinguish between red and green, so at a traffic light they can tell which light is “on” by its intensity, but they must rely on the position of the bright light to know whether to stop or go. Colour blindness is often genetic in nature, but also may result from eye, nerve, or brain damage.

Although the three-cone system has been accepted as the standard model of colour vision for more than two centuries, new evidence suggests that perception of colour may be more complex. DNA studies have shown that men with normal colour vision have a variable number of genes coding for cone pigments. For example, many had multiple genes (from two to four) for red-light detection, and these men could distinguish more subtle differences in colours in this long-wavelength range than could those with single copies of red-cone genes. This finding will undoubtedly lead to a re-evaluation of how the various photopigments contribute to colour vision.

Visual information

The field of view that can be seen without moving the head is known as the **visual field**. The information that reaches the visual cortex in the occipital lobe is not a replica of the visual field for several reasons:

▶ **FIGURE 4-21** Sensitivity of the three types of cones to different wavelengths. The ratios of stimulation of the three cone types are shown for three sample colours.

► **FIGURE 4-22** Colour blindness chart. People with red–green colour blindness cannot detect the number 29 in this chart.

4

The image detected on the retina at the onset of visual processing is upside down and backward because of bending of the light rays through the lens of the eye. Once projected to the brain, the inverted image is interpreted as being in its correct orientation.

The information transmitted from the retina to the brain is not merely a point-to-point record of photoreceptor activation. Before the information reaches the brain, the retinal neuronal layers beyond the rods and cones reinforce selected information and suppress other information to enhance contrast. One mechanism of retinal processing is lateral inhibition, by which strongly excited cone pathways suppress activity in surrounding pathways of weakly stimulated cones. This increases the dark–bright contrast to enhance the sharpness of boundaries.

Another mechanism of retinal processing involves differential activation of two types of ganglion cells: **on-centre and off-centre ganglion cells**. The receptive field of a cone ganglion cell is determined by the field of light detection by the cone with which it is linked. On-centre and off-centre ganglion cells respond in opposite ways, depending on the relative comparison of illumination between the centre and periphery of their receptive fields. Think of the receptive field as a doughnut. An on-centre ganglion cell increases its rate of firing when light is most intense at the centre of its receptive field (i.e., when the doughnut hole is lit up). In contrast, an off-centre cell increases its firing rate when the periphery of its receptive field is most intensely illuminated (i.e., when the doughnut itself is lit up). This is useful for enhancing the difference in light level between one small area at the centre of a receptive field and the illumination immediately around it. By emphasizing differences in relative brightness, this mechanism helps define contours of images, but in so doing, information about absolute brightness is sacrificed (► Figure 4-23).

Various aspects of visual information, such as form, colour, depth, and movement, are separated and projected in parallel pathways to different regions of the cortex. Only when these separate bits of processed information are integrated by higher visual

► **FIGURE 4-23** Example of the outcome of retinal processing by on-centre and off-centre ganglion cells. Note that the grey circle surrounded by black appears brighter than the one surrounded by white, even though the two circles are identical (same shade and size). Retinal processing by on-centre and off-centre ganglion cells is largely responsible for enhancing differences in relative (rather than absolute) brightness, which helps define contours.

regions do we perceive a reassembled picture of the visual scene. This is similar to the blobs of paint on an artist's palette versus the finished portrait; the separate pigments do not represent a portrait of a face until they are appropriately integrated on a canvas.

Patients with lesions in specific visual-processing regions of the brain may be unable to completely combine components of a visual impression. For example, a person may be unable to discern movement of an object but have reasonably good vision for shape, pattern, and colour. Sometimes the defect can be remarkably specific, like being unable to recognize familiar faces, while retaining the ability to recognize inanimate objects.

Because of the pattern of neural wiring between the eyes and the visual cortex, the left half of the cortex receives information only from the right half of the visual field as detected by both eyes, and the right half receives input only from the left half of the visual field of both eyes.

As light enters the eyes, light rays from the left half of the visual field fall on the right half of the retina of both eyes (the medial or inner half of the left retina and the lateral or outer half of the right retina) (► Figure 4-24a). Similarly, rays from the right half of the visual field reach the left half of each retina (the lateral half of the left retina and the medial half of the right retina). Each optic nerve exiting the retina carries information from both halves of the retina it serves. This information is separated as the optic nerves meet at the **optic chiasm** located underneath the hypothalamus (*chiasm* means “cross”) (see Figure 3-7b). Within the optic chiasm, the fibres from the medial half of each retina cross to the opposite side, but those from the lateral half remain on the original side. The reorganized bundles of fibres leaving the optic chiasm are known as **optic tracts**. Each optic tract carries information from the lateral half of one retina and the medial half of the other retina. Therefore, this partial crossover brings together from the two eyes fibres that carry information from the same half of the visual field. Each optic tract, in turn, delivers to the half of the brain on its same side information about the opposite half of the visual field.

Knowledge of these pathways can facilitate diagnosis of visual defects arising from an interruption of the visual pathway at various points (► Figure 4-24b).

Before we move on to how the brain processes visual information, take a look at ■ Table 4-4, which summarizes the functions of the various components of the eyes.

FIGURE 4-24 The visual pathway and visual deficits associated with lesions in the pathway. (a) Note that the left half of the visual cortex in the occipital lobe receives information from the right half of the visual field of both eyes (in blue), and the right half of the cortex receives information from the left half of the visual field of both eyes (in red). (b) Each visual deficit illustrated is associated with a lesion at the corresponding numbered point in the visual pathway in part (a).

Clinical Connections

Because Deborah is diabetic, her reported visual disturbances are likely due to diabetic retinopathy. In retinopathy, the microvasculature supplying the retina can weaken and leak blood, causing swelling in the retina. This can cause the blurred vision and minor vision loss that is experienced in about 25 percent of those with diabetes mellitus. As the disease progresses, the blood vessel injury gets worse, and decreases blood supply to the retina, in a manner similar to that underlying the neuropathy already discussed. Eventually this leads to severe vision loss and even blindness.

The thalamus and visual cortices

The first stop in the brain for information in the visual pathway is the lateral geniculate nucleus in the thalamus (► Figure 4-24a). It separates information received from the eyes and relays it via fibre bundles—known as **optic radiations**—to different zones in the cortex, each of which processes different aspects of the visual stimulus (e.g., colour, form, depth, movement). This sorting process is no small task, because each optic nerve contains more than a million fibres carrying information from the photoreceptors in one retina. This is more than all the afferent fibres carrying somatosensory input from all other regions of the body! Researchers estimate that hundreds of millions of neurons, occupying about 30 percent of the cortex, participate in visual processing, compared with 8 percent devoted to touch perception and 3 percent to hearing. Yet the connections in the visual pathways are precise. The lateral geniculate nucleus and each of

the zones in the cortex that processes visual information have a topographical map representing the retina point for point. As with the somatosensory cortex, the neural maps of the retina are distorted. The fovea, the retinal region capable of greatest acuity, has much greater representation in the neural map than do the more peripheral regions of the retina.

DEPTH PERCEPTION

Although each half of the visual cortex receives information simultaneously from the same part of the visual field as received by both eyes, the messages from the two eyes are not identical. Each eye views an object from a slightly different vantage point, even though the overlap is tremendous. The overlapping area seen by both eyes at the same time is known as the **binocular field of vision** (*binocular* means “two-eyed”), which is important for **depth perception**. Like other areas of the cortex, the primary visual cortex is organized into functional columns, each processing information from a small region of the retina. Independent, alternating columns are devoted to information about the same point in the visual field from the right and left eyes. The brain uses the slight disparity in the information received from the two eyes to estimate distance, allowing you to perceive three-dimensional objects in spatial depth. Nevertheless, some depth perception is possible using only one eye, based on experience and comparison with other cues. For example, if your one-eyed view includes a car and a building and the car is much larger, you correctly interpret that the car must be closer to you than the building is.

TABLE 4-4 Functions of the Major Components of the Eye

Structure	Location	Function
(in alphabetical order)		
Aqueous Humour	Anterior cavity between cornea and lens	Clear watery fluid that is continually formed and carries nutrients to the cornea and lens
Bipolar Cells	Middle layer of nerve cells in retina	Important in retinal processing of light stimulus
Blind Spot	Point slightly off centre on retina where optic nerve exits; is devoid of photoreceptors (also known as <i>optic disc</i>)	Route for passage of optic nerve and blood vessels
Choroid	Middle layer of eye	Pigmented to prevent scattering of light rays in eye; contains blood vessels that nourish retina; anteriorly specialized to form ciliary body and iris
Ciliary Body	Specialized anterior derivative of the choroid layer; forms a ring around the outer edge of the lens	Produces aqueous humour and contains ciliary muscle
Ciliary Muscle	Circular muscular component of ciliary body; attached to lens by means of suspensory ligaments	Important in accommodation
Cones	Photoreceptors in outermost layer of retina	Responsible for high acuity, colour, and day vision
Cornea	Anterior clear outermost layer of eye	Contributes most extensively to eye's refractive ability
Fovea	Exact centre of retina	Region with greatest acuity
Ganglion Cells	Inner layer of nerve cells in retina	Important in retinal processing of light stimulus; form optic nerve
Iris	Visible pigmented ring of muscle within aqueous humour	Varies size of pupil by variable contraction; responsible for eye colour
Lens	Between aqueous humour and vitreous humour; attaches to ciliary muscle by suspensory ligaments	Provides variable refractive ability during accommodation
Macula Lutea	Area immediately surrounding the fovea	Has high acuity because of abundance of cones
Optic Disc	(see entry for <i>blind spot</i>)	
Optic Nerve	Leaves each eye at optic disc (blind spot)	First part of visual pathway to the brain
Pupil	Anterior round opening in middle of iris	Permits variable amounts of light to enter eye
Retina	Innermost layer of eye	Contains the photoreceptors (rods and cones)
Rods	Photoreceptors in outermost layer of retina	Responsible for high-sensitivity, black-and-white, and night vision
Sclera	Tough outer layer of eye anteriorly specialized to form cornea	Protective connective tissue coat; forms visible white part of eye
Suspensory Ligaments	Suspended between ciliary muscle and lens	Important in accommodation
Vitreous Humour	Between lens and retina	Semifluid, jelly-like substance that helps maintain spherical shape of eye

© 2016 Cengage

Clinical Note Sometimes the two views are not successfully merged. This condition may occur for two reasons: (1) the eyes are not both focused on the same object simultaneously, because of defects of the external eye muscles that make fusion of the two eyes' visual fields impossible; or (2) the binocular information is improperly integrated during visual processing. The result is double vision, or **diplopia**, a condition in which the disparate views from both eyes are seen simultaneously.

HIERARCHY OF VISUAL CORTICAL PROCESSING

Within the cortex, visual information is first processed in the primary visual cortex and then sent to higher-level visual areas for even more complex processing and abstraction. The cortex contains a hierarchy of visual cells that respond to increasingly complex stimuli. Three types of visual cortical neurons have been identified based on the complexity of stimulus required for the cell to respond; these are called **simple cells**, **complex cells**,

and **hypercomplex cells**. Simple and complex cells are stacked on top of one another within the cortical columns of the primary visual cortex, whereas hypercomplex cells are found in the higher visual-processing areas. Unlike a retinal cell, which responds to the amount of light, a cortical cell fires only when it receives information regarding a particular pattern of illumination for which it is programmed. These patterns are built up by converging connections that originate from closely aligned photoreceptor cells in the retina. For example, some simple cells fire only when a bar is viewed vertically in a specific location, others when a bar is horizontal, and others at various oblique orientations. Movement of a critical axis of orientation becomes important for responses generated by some of the complex cells. Hypercomplex cells add a new dimension to visual processing by responding only to particular edges, corners, and curves.

Each level of cortical visual neurons has increasingly greater capacity for abstraction based on information built up from the increasing convergence of input from lower-level neurons. In this way, the cortex transforms the dot-like pattern of photoreceptors stimulated to varying degrees by varying light intensities in the retinal image into information about depth, position, orientation, movement, contour, and length. Other aspects of this information, such as colour perception, are processed simultaneously. How and where the entire image is finally put together is still unresolved. Only when the higher visual regions integrate these separate bits of processed information do we perceive a reassembled picture of the visual scene.

Visual input to other areas of the brain

Not all fibres in the visual pathway terminate in the visual cortices. Some are projected to other regions of the brain for purposes other than direct vision perception. Examples of nonsight activities dependent on input from the rods and cones include (1) contribution to cortical alertness and attention, (2) control of pupil size, and (3) control of eye movements. Each eye is equipped with a set of six **external eye muscles** that position and move the eye so that it can better locate, see, and track objects. Eye movements are among the fastest, most discretely controlled movements of the body.

MULTIPLE SENSORY-PROCESSING AREAS IN THE BRAIN

Before concluding this section on the eye, consider a controversial new theory regarding the senses—one that challenges the prevailing view that the separate senses feed into distinct brain regions that handle only one sense. A growing body of evidence suggests that the brain regions devoted almost exclusively to a certain sense, such as the visual cortex for visual input and the somatosensory cortex for touch input, actually receive a variety of sensory signals. Therefore, tactile and auditory signals also arrive in the visual cortex. For example, one study using new brain-imaging techniques showed that people who are blind from birth use the visual cortex when they read Braille, even though they are not “seeing” anything. The tactile input from their fingers reaches the visual area of the brain as well as the somatosensory cortex. This input helps them “visualize” the patterns of the Braille bumps.

Also reinforcing the notion that central processing of different types of sensory input overlaps to some extent, scientists recently discovered *multisensory neurons*—brain cells that react to multiple sensory inputs instead of just to one. No one knows whether these cells are rare or commonplace in the brain.

Next, we concentrate on the mainstream functions of the other special senses. Let’s shift attention from the eyes to the ears.

1. Draw two sagittal sections of an emmetropic eye, one for far vision and one accommodated for near vision.
2. Explain how light absorption by a photopigment leads to a hyperpolarizing receptor potential.
3. Compare rod and cone vision.

4.6 | Ear: Hearing and Equilibrium

Each **ear** consists of three parts: the *external*, the *middle*, and the *inner ear* (► Figure 4-25). The external and middle portions of the ear transmit airborne sound waves to the fluid-filled inner ear, amplifying the sound energy in the process. The inner ear houses two different sensory systems: the *cochlea*, which contains the receptors for conversion of sound waves into nerve impulses, making hearing possible; and the *vestibular apparatus*, which is necessary for the sense of equilibrium.

Sound waves

Hearing is the neural perception of sound energy. Hearing involves two aspects: identification of the sounds (what) and their localization (where). We first describe the characteristics of sound waves, and then we examine how the ears and brain process sound input to accomplish hearing.

Sound waves are travelling vibrations of air that consist of regions of high pressure, caused by compression of air molecules, alternating with regions of low pressure, caused by rarefaction of the molecules (► Figure 4-26a). Any device capable of producing such a disturbance pattern in air molecules is a source of sound. A simple example is a tuning fork. When a tuning fork is struck, its prongs vibrate. As a prong of the fork moves in one direction (► Figure 4-26b), air molecules ahead of it are pushed closer together, or compressed, increasing the pressure in this area. Simultaneously, as the prong moves forward, the air molecules behind the prong spread out, or are rarefied, lowering the pressure in that region. As the prong moves in the opposite direction, an opposite wave of compression and rarefaction is created. Even though individual molecules are moved only short distances as the tuning fork vibrates, alternating waves of compression and rarefaction spread out considerable distances in a rippling fashion. Disturbed air molecules disturb other molecules in adjacent regions, setting up new regions of compression and rarefaction, and so on (► Figure 4-26c). Sound energy

FIGURE 4-26 Formation of sound waves. (a) Sound waves are alternating regions of compression and rarefaction of air molecules. (b) A vibrating tuning fork sets up sound waves as the air molecules ahead of the advancing arm of the tuning fork are compressed and the molecules behind the arm are rarefied. (c) Disturbed air molecules bump into molecules beyond them, setting up new regions of air disturbance more distant from the original source of sound. In this way, sound waves travel progressively farther from the source, even though each individual air molecule travels only a short distance when it is disturbed. The sound wave dies out when the last region of air disturbance is too weak to disturb the region beyond it.

is gradually dissipated as sound waves travel farther from the original sound source. The intensity of the sound decreases, until it finally dies out when the last sound wave is too weak to disturb the air molecules around it.

Sound waves can also travel through media other than air, such as water. They do so less efficiently, however; greater pressures are required to cause movements of fluid than movements of air because of the fluid's greater inertia (resistance to change).

Sound is characterized by its pitch (tone), intensity (loudness), and timbre (quality) (► Figure 4-27):

- The **pitch**, or **tone**, of a sound (e.g., whether it is a C or a G note) is determined by the frequency of vibrations. The greater the frequency of vibration is, the higher the pitch. Human ears can detect sound waves with frequencies from 20 to 20 000 cycles per second but are most sensitive to frequencies between 1000 and 4000 cycles per second.
- The intensity, or **loudness**, of a sound depends on the amplitude of the sound waves, which is the pressure difference between a high-pressure region of compression and a low-pressure region of rarefaction. Within the hearing range, the greater the amplitude is, the louder the sound. Human ears can detect a wide range of sound intensities, from the slightest whisper to the painfully loud takeoff of a jet. Loudness is measured in decibels (dB), which are a logarithmic measure of intensity compared with the faintest sound that can be heard: the **hearing threshold**. Because of the logarithmic relationship, every 10 dB indicates a tenfold increase in loudness. A few examples of common sounds illustrate the magnitude of these increases (■ Table 4-5). Note that the rustle of leaves at 10 dB is 10 times as loud as hearing threshold, but the sound of a jet taking off at 150 dB is a quadrillion (a million billion) times, not 150 times, as loud as the faintest audible sound. Sounds greater than 100 dB can permanently damage the sensitive sensory apparatus in the cochlea.
- The **timbre**, or **quality**, of a sound depends on its overtones, which are additional frequencies superimposed on the fundamental pitch or tone. A tuning fork has a pure tone, but most sounds lack purity. For example, complex mixtures of overtones impart different sounds to different instruments

■ **TABLE 4-5** Relative Magnitude of Common Sounds

Sound	Loudness (in dB)	Comparison with Faintest Audible Sound (Hearing Threshold)
Rustle of leaves	10	10 times as loud
Ticking of watch	20	100 times as loud
Hush of library	30	1 thousand times as loud
Normal conversation	60	1 million times as loud
Food blender	90	1 billion times as loud
Loud rock concert	120	1 trillion times as loud
Takeoff of jet plane	150	1 quadrillion times as loud

playing the same note (a C note on a trumpet sounds different from C on a piano). Overtones are likewise responsible for characteristic differences in voices. Timbre enables the listener to distinguish the source of sound waves, because each source produces a different pattern of overtones.

The external ear

The specialized receptors for sound are located in the fluid-filled inner ear. Airborne sound waves must therefore be channelled toward and transferred into the inner ear, compensating in the process for the loss in sound energy that naturally occurs as sound waves pass from air into water. This function is performed by the external ear and the middle ear.

The **external ear** (see ► Figure 4-25) consists of the *pinna* (ear), *external auditory meatus* (ear canal), and *tympanic membrane* (eardrum). The **pinna**, a prominent skin-covered flap of cartilage, collects sound waves and channels them down the external ear canal. Many species (dogs, for example) can cock their ears in the direction of sound to collect more sound waves, but human ears are relatively immobile. Because of its shape, the pinna partially shields sound waves that approach the ear from the rear, changing the timbre of the sound and thus helping a person distinguish whether a sound is coming from directly in front or behind.

Sound localization for sounds approaching from the right or left is determined by two cues. First, the sound wave reaches the ear closer to the sound source slightly before it arrives at the farther ear. Second, the sound is less intense as it reaches the farther ear, because the head acts as a sound barrier that partially disrupts the propagation of sound waves. The

► **FIGURE 4-27** Properties of sound waves

auditory cortex integrates all these cues to determine the location of the sound source. It is difficult to localize sound with only one ear. Recent evidence suggests that the auditory cortex pinpoints the location of a sound by differences in the timing of neuronal firing patterns, not by any spatially organized map, such as the one projected on the visual cortex point for point from the retina that enables the location of a visual object to be identified.

The entrance to the **ear canal** is guarded by fine hairs. The skin lining the canal contains modified sweat glands that produce **cerumen** (earwax), a sticky secretion that traps fine foreign particles. Together, the hairs and earwax help prevent airborne particles from reaching the inner portions of the ear canal, where they could accumulate or injure the tympanic membrane and interfere with hearing.

The tympanic membrane

The **tympanic membrane**, which is stretched across the entrance to the middle ear, vibrates when struck by sound waves. The alternating higher- and lower-pressure regions of a sound wave cause the exquisitely sensitive eardrum to bow inward and outward in unison with the wave's frequency.

For the membrane to be free to move as sound waves strike it, the resting air pressure on both sides of the tympanic membrane must be equal. The outside of the eardrum is exposed to atmospheric pressure that reaches it through the ear canal. The inside of the eardrum facing the middle ear cavity is also exposed to atmospheric pressure via the **eustachian (auditory) tube**, which connects the middle ear to the **pharynx** (back of the throat) (see ▶ Figure 4-25). The eustachian tube is normally closed, but it can be pulled open by yawning, chewing, and swallowing. Such opening permits air pressure within the middle ear to equilibrate with atmospheric pressure so that pressures on both sides of the tympanic membrane are equal. During rapid external pressure changes (e.g., during air flight), the eardrum bulges painfully as the pressure outside the ear changes while the pressure in the middle ear remains unchanged. Opening the eustachian tube by yawning allows the pressure on both sides of the tympanic membrane to equalize, relieving the pressure distortion as the eardrum “pops” back into place.

Clinical Note Infections originating in the throat sometimes spread through the eustachian tube to the middle ear. The resulting fluid accumulation in the middle ear not only is painful but also interferes with sound conduction across the middle ear.

The middle ear bones

The **middle ear** transfers the vibratory movements of the tympanic membrane to the fluid of the inner ear. This transfer is facilitated by a movable chain of three small bones, or **ossicles** (the **malleus**, **incus**, and **stapes**), that extend across the middle ear (▶ Figure 4-28a). The first bone, the malleus, is attached to the tympanic membrane, and the last bone, the stapes, is attached to the **oval window**, the entrance into the fluid-filled cochlea. As the tympanic membrane vibrates in response to sound waves, the

chain of bones is set into motion at the same frequency, transmitting this frequency of movement from the tympanic membrane to the oval window. The resulting pressure on the oval window with each vibration produces wavelike movements in the inner ear fluid at the same frequency as the original sound waves. However, as noted earlier, greater pressure is required to set fluid in motion.

The ossicular system amplifies the pressure of the airborne sound waves by two mechanisms to set up fluid vibrations in the cochlea. First, because the surface area of the tympanic membrane is much larger than that of the oval window, pressure is increased as the force exerted on the tympanic membrane is conveyed by the ossicles to the oval window (pressure 5 force/unit area). Second, the lever action of the ossicles provides an additional mechanical advantage. Together, these mechanisms increase the force exerted on the oval window by 20 times what it would be if the sound wave struck the oval window directly. This additional pressure is sufficient to set the cochlear fluid in motion.

Several tiny muscles in the middle ear contract reflexively in response to loud sounds (more than 70 dB), causing the tympanic membrane to tighten and limiting movement of the ossicular chain. This reduced movement of middle ear structures diminishes the transmission of loud sound waves to the inner ear to protect the delicate sensory apparatus from damage. This reflex response is relatively slow, however, happening at least 40 milliseconds after exposure to a loud sound. It thus provides protection only from prolonged loud sounds, not from sudden sounds like an explosion. Taking advantage of this reflex, World War II anti-aircraft guns were designed to make a loud pre-firing sound to protect the gunner's ears from the much louder boom of the actual firing.

The cochlea

The pea-sized, snail-shaped **cochlea**, the “hearing” portion of the inner ear, is a coiled tubular system lying deep within the temporal bone (see ▶ Figure 4-25). It is easier to understand the functional components of the cochlea by “unrolling” it, as shown in ▶ Figure 4-28a. The cochlea is divided throughout most of its length into three fluid-filled longitudinal compartments. A blind-ended **cochlear duct**, also known as the **scala media**, constitutes the middle compartment. It tunnels lengthwise through the centre of the cochlea, almost but not quite reaching its end. The upper compartment, the **scala vestibuli**, follows the inner contours of the spiral, and the **scala tympani**, the lower compartment, follows the outer contours (▶ Figure 4-28a and 4-28b). The fluid within the cochlear duct is called **endolymph** (Figure 4-29a). The scala vestibuli and scala tympani both contain a slightly different fluid, the **perilymph**. The region beyond the tip of the cochlear duct where the fluid in the upper and lower compartments is continuous is called the **helicotrema**. The scala vestibuli is sealed from the middle ear cavity by the oval window, to which the stapes is attached. Another small membrane-covered opening, the **round window**, seals the scala tympani from the middle ear. The thin **vestibular membrane** forms the ceiling of the cochlear duct and separates it from the scala vestibuli. The **basilar membrane**

forms the floor of the cochlear duct, separating it from the scala tympani. The basilar membrane is especially important because it bears the **organ of Corti**, the sense organ for hearing.

Hair cells

The organ of Corti, which rests on top of the basilar membrane throughout its full length, contains **hair cells** that are the receptors for sound. The 16 000 hair cells within each cochlea are arranged in four parallel rows along the length of the basilar membrane: one row of **inner hair cells**, and three

rows of **outer hair cells** (► Figure 4-28c). Protruding from the surface of each hair cell are about 100 hairs known as **stereocilia**, which are actin-stiffened microvilli. Hair cells generate neural signals when their surface hairs are mechanically deformed in association with fluid movements in the inner ear. These stereocilia contact the **tectorial membrane**, an awning-like projection overhanging the organ of Corti throughout its length (► Figure 4-28b and ► 4-28c).

The piston-like action of the stapes against the oval window sets up pressure waves in the upper compartment. Because fluid is incompressible, pressure is dissipated in two ways as the stapes

causes the oval window to bulge inward: (1) displacement of the round window, which dissipates sound energy; and (2) deflection of the basilar membrane, which allows for sound reception (► Figure 4-29a). In the first of these pathways, the pressure wave pushes the perilymph forward in the upper compartment, then around the helicotrema, and into the lower compartment, where it causes the round window to bulge outward into the middle ear cavity to compensate for the pressure increase. As the stapes rocks backward and pulls the oval window outward toward the middle ear, the perilymph shifts in the opposite direction, displacing the round window inward. This pathway does not result in sound reception; it just dissipates pressure.

The second pathway involves the deflection of the basilar membrane and results in sound reception. Pressure waves in the upper compartment are transferred through the thin vestibular membrane, into the cochlear duct, and then through the basilar membrane into the lower compartment, where they cause the round window to alternately bulge outward and inward. The main difference in this pathway is that transmission of pressure waves through the basilar membrane causes this membrane to move up and down, or vibrate, in synchrony with the pressure wave. Because the organ of Corti rides on the basilar membrane, the hair cells also move up and down as the basilar membrane oscillates; this movement initiates sound reception.

ROLE OF THE INNER HAIR CELLS

The inner and outer hair cells differ in function. The inner hair cells transform the mechanical forces of sound (cochlear fluid vibration) into the electrical impulses of hearing (action potentials propagating auditory messages to the cerebral cortex). The outer hair cells function to enhance the response of the inner hair cells.

Because the stereocilia of the inner hair receptor cells contact the stiff, stationary tectorial membrane, they are bent back and forth when the oscillating basilar membrane shifts their position in relationship to the tectorial membrane (► Figure 4-30). This back-and-forth mechanical deformation of the hairs alternately opens and closes mechanically gated ion channels in the hair cell, resulting in alternating depolarizing and hyperpolarizing potential changes—the receptor potential—at the same frequency as the original sound stimulus.

The inner hair cells communicate via a chemical synapse with the terminals of afferent nerve fibres making up the **auditory (cochlear) nerve**. Depolarization of these hair cells (when the basilar membrane is deflected upward) increases their rate of neurotransmitter release, which steps up the rate of firing in the afferent fibres. Conversely, the firing rate decreases as these hair cells release less neurotransmitter when they are hyperpolarized upon displacement in the opposite direction.

Thus, the ear converts sound waves in the air into oscillating movements of the basilar membrane that bend the hairs of the receptor cells back and forth. This shifting mechanical deformation of the hairs alternately opens and closes the receptor cells' channels, bringing about graded potential changes in the receptor that lead to changes in the rate of action potentials propagated to the brain. In this way, sound waves are translated into neural signals that can be perceived by the brain as sound sensations (► Figure 4-31).

ROLE OF THE OUTER HAIR CELLS

Whereas the inner hair cells send auditory signals to the brain through afferent fibres, the outer hair cells do not signal the brain about incoming sounds. Instead, the outer hair cells actively and rapidly change length in response to changes in membrane potential, a behaviour known as *electromotility*. The outer hair cells shorten on depolarization and lengthen on hyperpolarization. These changes in length amplify, or accentuate, the motion of the basilar membrane. An analogy would be a person deliberately pushing the pendulum of a grandfather clock in time with its swing to accentuate its motion. Such modification of basilar membrane movement improves and fine tunes the stimulation of the inner hair cells. Thus, the outer hair cells enhance the response of the inner hair cells—the real auditory sensory receptors—making them exquisitely sensitive to sound intensity and highly discriminatory between various pitches of sound.

Pitch discrimination

Pitch discrimination is the ability to distinguish between various frequencies of incoming sound waves. This capacity depends on the shape and properties of the basilar membrane, which is narrow and stiff at its oval window end and wide and flexible at its helicotrema end (see ► Figure 4-29b). Different regions of the basilar membrane naturally vibrate maximally at different frequencies; that is, each frequency displays peak vibration at a different position along the membrane. The narrow end nearest the oval window vibrates best with high-frequency pitches, whereas the wide end nearest the helicotrema vibrates maximally with low-frequency tones (see ► Figure 4-29c). The pitches in between are sorted out precisely along the length of the membrane from higher to lower frequency. When a sound wave of a particular frequency is set up in the cochlea by oscillation of the stapes, the wave travels to the region of the basilar membrane that naturally responds maximally to that frequency. The vigorous membrane oscillation dissipates the energy of the pressure wave, so the wave dies out at the region of maximal displacement.

The hair cells in the region of peak vibration of the basilar membrane undergo the most mechanical deformation and accordingly are the most excited. This information is propagated to the CNS, which interprets the pattern of hair cell stimulation as a sound of a particular frequency. Modern techniques have determined that the basilar membrane is so fine-tuned that the peak membrane response to a single pitch probably extends no more than the width of a few hair cells.

Loudness discrimination

Intensity (loudness) discrimination depends on the amplitude of vibration. As sound waves originating from a loud sound source strikes the eardrum, they cause it to vibrate more vigorously (i.e., bulge in and out to a greater extent) but at the same frequency as a softer sound of the same pitch. Consequently, the greater tympanic membrane deflection is converted into a greater amplitude of basilar membrane movement in the region of peak responsiveness. The CNS interprets greater basilar membrane oscillation as a louder sound.

Fluid movement within the perilymph set up by vibration of the oval window follows two pathways:

Pathway 1 Through the scala vestibuli, around the helicotrema, and through the scala tympani, causing the round window to vibrate. This pathway just dissipates sound energy.

Pathway 2 A "shortcut" from the scala vestibuli through the basilar membrane to the scala tympani. This pathway triggers activation of the receptors for sound by bending the hairs of hair cells as the organ of Corti on top of the vibrating basilar membrane is displaced in relation to the overlying tectorial membrane.

The numbers indicate the frequencies in cycles per second with which different regions of the basilar membrane maximally vibrate.

(a)

(c)

FIGURE 4-29 Transmission of sound waves. (a) Fluid movement within the cochlea set up by vibration of the oval window follows two pathways, one dissipating sound energy and the other initiating the receptor potential. (b) Different regions of the basilar membrane vibrate maximally at different frequencies. (c) The narrow, stiff end of the basilar membrane nearest the oval window vibrates best with high-frequency pitches. The wide, flexible end of the basilar membrane near the helicotrema vibrates best with low-frequency pitches.

The stereocilia (hairs) from the hair cells of the basilar membrane contact the overlying tectorial membrane. These hairs are bent when the basilar membrane is deflected in relation to the stationary tectorial membrane. This bending of the inner hair cells' hairs opens mechanically gated channels, leading to ion movements that result in a receptor potential.

© 2016 Cengage

► FIGURE 4-30 Bending of hairs on deflection of the basilar membrane

The auditory system is so sensitive and can detect sounds so faint that the distance of basilar membrane deflection is comparable to only a fraction of the diameter of a hydrogen atom, the smallest of atoms. No wonder that very loud sounds—which cannot be sufficiently attenuated by protective middle ear reflexes (e.g., the sounds of a typical rock concert)—can set up such violent vibrations of the basilar membrane that irreplaceable hair cells are actually sheared off or permanently distorted, leading to partial hearing loss (► Figure 4-32).

The auditory cortex

Just as various regions of the basilar membrane are associated with particular tones, the **primary auditory cortex** in the temporal lobe is also *tonotopically* organized. Each region of the basilar membrane is linked to a specific region of the primary auditory cortex. Accordingly, specific cortical neurons are activated only by particular tones; that is, each region of the auditory cortex becomes excited only in response to a specific tone detected by a selected portion of the basilar membrane.

The afferent neurons that pick up the auditory signals from the inner hair cells exit the cochlea via the auditory nerve. The neural pathway between the organ of Corti and the auditory cortex involves several synapses en route, the most notable of which are in the brain stem and *medial geniculate nucleus* of the thalamus. The brain stem uses the auditory input for alertness and arousal. The thalamus sorts and relays the signals upward. Unlike signals in the visual pathways, auditory signals from each ear are transmitted to both temporal lobes because the fibres partially cross over in the brain stem. For this reason, a disruption of the auditory pathways on one side above the brain stem does not affect hearing in either ear to any extent.

© 2016 Cengage

► FIGURE 4-31 Sound transduction

The primary auditory cortex appears to perceive discrete sounds, whereas the surrounding higher-order auditory cortex integrates the separate sounds into a coherent, meaningful pattern. Think about the complexity of the task accomplished by your auditory system. When you are at a

concert, your organ of Corti responds to the simultaneous mixture of the instruments, the applause and hushed talking of the audience, and the background noises in the theatre. You can distinguish these separate parts of the many sound waves reaching your ears and can pay attention to those of importance to you.

Deafness

Loss of hearing, or **deafness**, may be temporary or permanent, partial or complete. Hearing loss, which affects about 8 percent of all Canadians, is the second most common physical disability in the United States. Deafness is classified into two types—*conductive deafness* and *sensorineural deafness*—depending on the part of the hearing mechanism that fails to function adequately. **Conductive deafness** occurs when sound waves are not adequately conducted through the external and middle portions of the ear to set the fluids in the inner ear in motion. Possible causes include physical blockage of the ear canal with earwax, rupture of the eardrum, middle ear infections with accompanying fluid accumulation, or restriction of ossicular movement because of bony adhesions between the stapes and oval window. In **sensorineural deafness**, sound waves are transmitted to the inner ear, but they are not translated into nerve signals that are interpreted by the brain as sound sensations. The defect can lie in the organ of Corti or the auditory nerves or, rarely, in the ascending auditory pathways or auditory cortex.

One of the most common causes of partial hearing loss, **neural presbycusis**, is a degenerative, age-related process that occurs as hair cells “wear out” with use. Over time, exposure to even ordinary modern-day sounds eventually damages hair cells so that, on average, adults have lost more than 40 percent of their cochlear hair cells by age 65. Unfortunately, partial hearing loss caused by excessive exposure to loud noises is affecting people at younger ages than in the past, not only because we live in an increasingly noisy environment but also because of the increased use of earbuds and earphones associated with mobile phones and music devices like MP3 players. Hair cells that process high-frequency sounds are the most vulnerable to destruction.

Hearing aids are helpful in conductive deafness but are less beneficial for sensorineural deafness. These devices increase the intensity of airborne sounds and may modify the sound spectrum and tailor it to the person’s particular pattern of hearing loss at higher or lower frequencies. For the sound to be perceived, however, the receptor cell–neural pathway system must still be intact.

In recent years, **cochlear implants** have become available. These electronic devices, which are surgically implanted, transduce sound signals into electrical signals that can directly stimulate the auditory nerve, thus bypassing a defective cochlear system. Cochlear implants cannot restore normal hearing, but they do permit recipients to recognize sounds. Success ranges from an ability to “hear” a phone ringing to being able to carry on a conversation over the telephone.

Exciting new findings suggest that in the future it may be possible to restore hearing by stimulating an injured inner ear to repair itself. Scientists have long considered the hair cells of the inner ear irreplaceable. Thus, hearing loss resulting from hair cell damage caused by the aging process or exposure to loud noises is considered permanent. Encouraging new studies suggest, on the contrary, that hair cells in the inner ear have the latent ability to regenerate in response to an appropriate chemical signal. Researchers are currently trying to develop a drug that will spur regrowth of hair cells, thereby repairing inner ear damage and hopefully restoring hearing. Other investigators are using neural growth factors to coax auditory nerve cell endings to resprout in the hopes of re-establishing lost neural pathways.

Spoken languages are developed in the early years of life. A hearing impairment can prevent not only the ability to talk but also the ability to understand the spoken word. By the time severely hearing-impaired children are diagnosed, they may have already developed problems with communication that hinder family socialization and social skills. Early diagnosis means that sign language can be taught at a young age, thus facilitating communication. In industrialized countries, hearing is evaluated during the newborn period in an attempt to prevent the isolation that is associated with deafness. Although sign language is a full communication system, literacy (the ability to read and write)

➤ **FIGURE 4-32 Loss of hair cells caused by loud noises.** Injury and loss of hair cells caused by intense noise. Portions of the organ of Corti, with its three rows of outer hair cells and one row of inner hair cells, from the inner ear of (a) a normal guinea pig and (b) a guinea pig after a 24-hour exposure to noise at 120 dB SPL (sound pressure level), a level approached by loud rock music

depends on understanding spoken language. In most written languages, the sound of the word is coded in symbols. However, a person who can hear early in life and learns to speak and read will retain the ability to read, even if significant hearing loss occurs later. In contrast, a person who had significant hearing impairment from a very early age will rarely be able to read well. Listening also plays an important role in learning a second language. Thus, early identification of a hearing impairment is key to learning spoken language.

The vestibular apparatus

In addition to its cochlear-dependent role in hearing, the inner ear has another specialized component, the **vestibular apparatus**. This part of the inner ear provides essential information for the sense of equilibrium and also for the coordination of head movements with eye and postural movements. The vestibular apparatus consists of two sets of structures lying within a tunnelled-out region of the temporal bone near the cochlea: the *semicircular canals* and the *otolith organs*, namely the *utricle* and *sacculle* (► Figure 4-33a).

The vestibular apparatus detects changes in position and motion of the head. As in the cochlea, all components of the vestibular apparatus contain endolymph and are surrounded by perilymph. Also, similar to the organ of Corti, the vestibular components each contain hair cells that respond to mechanical deformation triggered by specific movements of the endolymph. And like the auditory hair cells, the vestibular receptors may be either depolarized or hyperpolarized, depending on the direction of the fluid movement. Unlike information from the auditory system, much of the information provided by the vestibular apparatus does not reach the level of conscious awareness.

ROLE OF THE SEMICIRCULAR CANALS

The **semicircular canals** detect rotational or angular acceleration or deceleration of the head, such as when starting or stopping spinning, somersaulting, or turning the head. Each ear contains three semicircular canals arranged three-dimensionally in planes that lie at right angles to each other. The receptive hair cells of each semicircular canal are situated on top of a ridge located in the **ampulla**, a swelling at the base of the canal (Figure 4-33a and 4-33b). The hairs are embedded in an overlying, caplike, gelatinous layer, the **cupula**, which protrudes into the endolymph within the ampulla. The cupula sways in the direction of fluid movement, much like seaweed leaning in the direction of the prevailing tide.

Acceleration or deceleration during rotation of the head in any direction causes endolymph movement in at least one of the semicircular canals, because of their three-dimensional arrangement. When you start to move your head, the bony canal and the ridge of hair cells embedded in the cupula move with your head. Initially, however, the fluid within the canal, not being attached to your skull, does not move in the direction of the rotation but lags behind because of its inertia. (Due to inertia, a resting object remains at rest, and a moving object continues to move in the same direction, unless the object is

acted on by some external force that induces change.) When the endolymph is left behind as you start to rotate your head, the fluid in the same plane as the head movement is in effect shifted in the opposite direction of the head movement (similar to your body tilting to the right as the car in which you are riding suddenly turns to the left) (► Figure 4-34). This fluid movement causes the cupula to lean in the opposite direction from the head movement, bending the sensory hairs embedded in it. If your head movement continues at the same rate in the same direction, the endolymph catches up and moves in unison with your head so that the hairs return to their unbent position. When your head slows down and stops, the reverse situation occurs. The endolymph briefly continues to move in the direction of the rotation while your head decelerates to a stop. As a result, the cupula and its hairs are transiently bent in the direction of the preceding spin, which is opposite to the way they were bent during acceleration.

The hairs of a vestibular hair cell consist of one cilium, the **kinocilium**, along with a tuft of 20 to 50 microvilli—the *stereocilia*—arranged in rows of increasing height (see ► Figure 4-33c and ► 4-33d). The stereocilia are linked at their tips by **tip links**, which are tiny molecular bridges between adjacent stereocilia. When the stereocilia are deflected by endolymph movement, the resultant tension on the tip links pulls on mechanically gated ion channels in the hair cell. Depending on whether the ion channels are mechanically opened or closed by hair bundle displacement, the hair cell either depolarizes or hyperpolarizes. Each hair cell is oriented so that it depolarizes when its stereocilia are bent toward the kinocilium; bending in the opposite direction hyperpolarizes the cell. The hair cells form chemically mediated synapses with terminal endings of afferent neurons whose axons join with those of the other vestibular structures to form the **vestibular nerve**. This nerve unites with the auditory nerve from the cochlea to form the **vestibulocochlear nerve**. Depolarization increases the release of neurotransmitter from the hair cells, thereby bringing about an increased rate of firing in the afferent fibres. Conversely, hyperpolarization reduces neurotransmitter release from the hair cells, in turn decreasing the frequency of action potentials in the afferent fibres. When the fluid gradually comes to a halt, the hairs straighten again. Thus, the semicircular canals detect changes in the rate of rotational movement (rotational acceleration or deceleration) of your head. They do not respond when your head is motionless or when it is moving in a circle at a constant speed.

ROLE OF THE OTOLITH ORGANS

The **otolith organs** provide information about the position of the head relative to gravity (i.e., static head tilt) and also detect changes in the rate of linear motion (moving in a straight line regardless of direction). The otolith organs, the **utricle** and the **sacculle**, are saclike structures housed within a bony chamber situated between the semicircular canals and the cochlea (see ► Figure 4-33a). The hairs (kinocilium and stereocilia) of the receptive hair cells in these sense organs also protrude into an overlying gelatinous sheet, whose movement displaces the hairs and results in changes in hair cell potential. Many tiny crystals of calcium

FIGURE 4-33 Vestibular apparatus. (a) Gross anatomy of the vestibular apparatus. (b) Receptor cell unit in the ampulla of the semicircular canals. (d) Scanning electron micrograph of the kinocilium and stereocilia on the hair cells within the vestibular apparatus

carbonate—the otoliths (ear stones)—are suspended within the gelatinous layer, making it heavier and giving it more inertia than the surrounding fluid (Figure 4-35a). When a person is in an upright position, the hairs within the utricles

are oriented vertically, and the saccule hairs are lined up horizontally.

Let's look at the *utricle* as an example. It's otolith-embedded, gelatinous mass shifts positions and bends the hairs in two ways:

► FIGURE 4-34 Activation of the hair cells in the semicircular canals

in the direction of the tilt of the head and in the opposite direction to the tilt.

1. The utricle hairs are displaced by any change in head movement away from the vertical. When you tilt your head in any direction other than vertical (i.e., other than straight up and down), the hairs are bent in the direction of the tilt because of the gravitational force exerted on the top-heavy gelatinous layer (► Figure 4-35b). This bending produces depolarizing or hyperpolarizing receptor potentials depending on the tilt of your head. The CNS thus receives different patterns of neural activity depending on head position with respect to gravity.

2. The utricle hairs are also displaced by any change in horizontal linear motion (such as moving straight forward, backward, or to the side). When you start to walk forward (► Figure 4-35c), the top-heavy otolith membrane at first lags behind the endolymph and hair cells because of its greater inertia. The hairs are thus bent to the rear, in the opposite direction of the forward movement of your head. If you maintain your walking pace, the gelatinous layer soon catches up and moves at the same rate as your head so that the hairs are no longer bent. When you stop walking, the otolith sheet continues to move forward briefly as your head slows and stops, bending the hairs toward the front. In this way, the hair cells of the utricle detect horizontally directed linear acceleration and deceleration, but they do not provide information about movement in a straight line at constant speed.

The *sacculle* functions similarly to the utricle, except that it responds selectively to tilting of the head away from a horizontal

position (such as getting up from bed) and to vertically directed linear acceleration and deceleration (such as jumping up and down or riding in an elevator).

Signals arising from the various components of the vestibular apparatus are carried through the vestibulocochlear nerve to the **vestibular nuclei**—a cluster of neuronal cell bodies in the brain stem—and to the cerebellum. Here, the vestibular information is integrated with input from the skin surface, eyes, joints, and muscles to accomplish three important functions: (1) maintaining balance and desired posture; (2) controlling the external eye muscles so that the eyes remain fixed on the same point, despite movement of the head; and (3) perceiving motion and orientation (► Figure 4-36).

Some people, for poorly understood reasons, are especially sensitive to particular motions that activate the vestibular apparatus and cause symptoms of dizziness and nausea; this sensitivity is called **motion sickness**. Occasionally, fluid imbalances within the inner ear lead to **Ménière's disease**. Not surprisingly, because both the vestibular apparatus and the cochlea contain the same inner ear fluids, both vestibular and auditory symptoms occur with this condition. An afflicted individual suffers transient attacks of severe vertigo (dizziness), accompanied by pronounced ringing in the ears and some loss of hearing. During these episodes, the person cannot stand upright and reports feeling as though self or surrounding objects in the room are spinning around.

Table 4-6 summarizes the functions of the major components of the ear.

4.7 Chemical Senses: Taste and Smell

Unlike the eyes' photoreceptors and the ears' mechanoreceptors, the receptors for taste and smell are chemoreceptors, which generate neural signals on binding with particular chemicals in their environment. The sensations of **taste** and **smell**

in association with food intake influence the flow of digestive juices and affect appetite. Furthermore, stimulation of taste or smell receptors induces pleasurable or objectionable sensations and signals the presence of something to seek (a nutritionally useful, good-tasting food) or to avoid (a potentially toxic, bad-tasting substance). In this way, the chemical senses provide a "quality-control" checkpoint for substances available for ingestion. In lower animals, smell also plays a major role in finding direction, in seeking prey or avoiding predators, and in sexual attraction to a mate. The sense of smell is less sensitive in humans and much less important in influencing our behaviour (although millions of dollars are spent annually on perfumes and deodorants to make us smell better and thereby more socially attractive).

We first examine the mechanism of taste (**gustation**) and then turn our attention to smell (**olfaction**).

Taste receptor cells

The chemoreceptors for taste sensation are packaged in taste buds, about 10 000 of which are present in the oral cavity and

FIGURE 4-36 Input and output of the vestibular nuclei

throat, with the greatest percentage on the upper surface of the tongue (► Figure 4-37). A taste bud consists of about 50 long, spindle-shaped *taste receptor cells* packaged with *supporting cells* in an arrangement like slices of an orange. Each taste bud has a small opening, the **taste pore**, through which fluids in the mouth come into contact with the surface of its receptor cells. **Taste receptor cells** are modified epithelial cells, with many surface folds (microvilli) that protrude slightly through the taste pore, greatly increasing the surface area exposed to the oral contents. The plasma membrane of the microvilli contains receptor sites that bind selectively with chemical molecules in the environment. Only chemicals in solution—either ingested liquids or solids that have been dissolved in saliva—can attach to receptor cells and evoke the sensation of taste. Binding of a taste-provoking chemical, a **tastant**, with a receptor cell alters the cell's ionic channels to produce a depolarizing receptor potential. This receptor potential, in turn, initiates action potentials within terminal endings of afferent nerve fibres with which the receptor cell synapses.

Most receptors are carefully sheltered from direct exposure to the environment, but the taste receptor cells, by virtue of their task, frequently come into contact with potent chemicals. Unlike the eye or ear receptors, which are irreplaceable, taste receptors have a life span of about 10 days. Epithelial cells surrounding the taste bud differentiate first into supporting cells and then into receptor cells to constantly renew the taste bud components.

Terminal afferent endings of several cranial nerves synapse with taste buds in various regions of the mouth. Signals in these sensory inputs are conveyed via synaptic stops in the brain stem and thalamus to the **cortical gustatory area**, a region in the parietal lobe adjacent to the “tongue” area of the somatosensory cortex. Unlike most sensory input, the gustatory pathways are

primarily uncrossed. The brain stem also projects fibres to the hypothalamus and limbic system to add affective dimensions, such as whether the taste is pleasant or unpleasant, and to process behavioural aspects associated with taste and smell.

Taste discrimination

We can discriminate among thousands of different taste sensations, yet all tastes are varying combinations of five **primary tastes**: *salty*, *sour*, *sweet*, *bitter*, and *umami*. Umami, a meaty or savoury taste, has recently been added to the list of primary tastes.

Each receptor cell responds in varying degrees to all five primary tastes but is generally preferentially responsive to one of the taste modalities. The richness of fine taste discrimination beyond the primary tastes depends on subtle differences in the stimulation patterns of all the taste buds in response to various substances, similar to the variable stimulation of the three cone types that gives rise to the range of colour sensations.

Receptor cells use different pathways to bring about a depolarizing receptor potential in response to each of the five tastant categories:

- **Salty taste** is stimulated by chemical salts, especially NaCl (table salt). Direct entry of positively charged Na^+ ions through specialized Na^+ channels in the receptor cell membrane, a movement that reduces the cell's internal negativity, is responsible for receptor depolarization in response to salt.
- **Sour taste** is caused by acids containing a free hydrogen ion (H^+). The citric acid content of lemons, for example, accounts for their distinctly sour taste. Depolarization of the receptor cell by sour tastants occurs because H^+ blocks

■ **TABLE 4-6** Functions of the Major Components of the Ear

Structure	Location	Function
External Ear		
<i>Pinna (ear)</i>	Skin-covered flap of cartilage located on each side of the head	Collects and transfers sound waves to the middle ear
<i>External auditory meatus (ear canal)</i>	Tunnels from the exterior through the temporal bone to the tympanic membrane	Collects sound waves and channels them down the ear canal; contributes to sound localization
<i>Tympanic membrane (eardrum)</i>	Thin membrane that separates the external ear and the middle ear	Directs sound waves to tympanic membrane; contains filtering hairs and secretes earwax to trap foreign particles
Middle Ear		Vibrates in synchrony with sound waves that strike it, setting middle ear bones in motion
		Transfers vibrations of the tympanic membrane to the fluid in the cochlea
<i>Malleus, incus, stapes</i>	Movable chain of bones that extends across the middle ear cavity; malleus attaches to the tympanic membrane, and stapes attaches to the oval window	Oscillate in synchrony with tympanic membrane vibrations and set up wavelike movements in the cochlear perilymph at the same frequency
Inner Ear: Cochlea		Houses sensory system for hearing
<i>Oval window</i>	Thin membrane at the entrance to the cochlea; separates the middle ear from the scala vestibuli	Vibrates in unison with movement of stapes, to which it is attached; oval window movement sets cochlear perilymph in motion
<i>Scala vestibuli</i>	Upper compartment of the cochlea, a snail-shaped tubular system that lies deep within the temporal bone	Contains perilymph that is set in motion by oval window movement driven by oscillation of middle ear bones
<i>Scala tympani</i>	Lower compartment of the cochlea	Contains perilymph that is continuous with the scala vestibuli
<i>Cochlear duct (scala media)</i>	Middle compartment of the cochlea; a blind-ended tubular compartment that tunnels through the centre of the cochlea	Contains endolymph; houses the basilar membrane
<i>Basilar membrane</i>	Forms the floor of the cochlear duct	Vibrates in unison with perilymph movements; bears the organ of Corti, the sense organ for hearing
<i>Organ of Corti</i>	Rests on top of the basilar membrane throughout its length	Contains hair cells, the receptors for sound; inner hair cells undergo receptor potentials when their hairs are bent as a result of fluid movement in cochlea
<i>Tectorial membrane</i>	Stationary membrane that overhangs the organ of Corti and contacts the surface hairs of the receptor hair cells	Serves as the stationary site against which the hairs of the receptor cells are bent to generate receptor potentials as the vibrating basilar membrane moves in relation to this overhanging membrane
<i>Round window</i>	Thin membrane that separates the scala tympani from the middle ear	Vibrates in unison with fluid movements in perilymph to dissipate pressure in cochlea; does not contribute to sound reception
Inner Ear: Vestibular Apparatus		Houses sensory systems for equilibrium and provides input essential for maintenance of posture and balance
<i>Semicircular canals</i>	Three semicircular canals arranged three-dimensionally in planes at right angles to each other near the cochlea	Detect rotational or angular acceleration or deceleration
<i>Utricle</i>	Saclike structure in a bony chamber between the cochlea and semicircular canals	Detects (1) changes in head position away from vertical and (2) horizontally directed linear acceleration and deceleration
<i>Sacculle</i>	Lies next to the utricle	Detects (1) changes in head position away from horizontal and (2) vertically directed linear acceleration and deceleration

► **FIGURE 4-37** Location and structure of the taste buds. Taste buds are located primarily along the edges of moundlike papillae on the upper surface of the tongue. The receptor cells and supporting cells of a taste bud are arranged like slices of an orange.

potassium (K^+) channels in the receptor cell membrane. The resultant decrease in the passive movement of positively charged K^+ out of the cell reduces the internal negativity, producing a depolarizing receptor potential.

- **Sweet taste** is evoked by the particular configuration of glucose. From an evolutionary perspective, we crave sweet foods because they supply necessary calories in a readily usable form. However, other organic molecules with similar structures but no calories, such as saccharin, aspartame, sucralose, and other artificial sweeteners, can also interact with “sweet” receptor binding sites. Binding of glucose or another chemical with the taste cell receptor activates a G protein, which turns on the cAMP second-messenger pathway in the taste cell (p. 217). The second-messenger pathway ultimately results in phosphorylation and blockage of K^+ channels in the receptor cell membrane, leading to a depolarizing receptor potential.
- **Bitter taste** is elicited by a more chemically diverse group of tastants than the other taste sensations. For example, alkaloids (such as caffeine, nicotine, strychnine, morphine, and other toxic plant derivatives), as well as poisonous substances, all taste bitter, presumably as a protective mechanism to discourage ingestion of these potentially dangerous compounds. Taste cells that detect bitter flavours possess 50 to 100 bitter receptors, each of which responds to a different bitter flavour. Because each receptor cell has this diverse family of bitter receptors, a wide variety of unrelated chemicals all taste bitter despite their diverse structures. This mechanism expands the ability of the taste receptor to detect a wide range of potentially harmful chemicals. The first G protein in taste—**gustducin**—was identified in one of the bitter-signalling pathways. This G protein, which sets off a second-messenger pathway in the taste cell, is very similar to the visual G protein, transducin.

- **Umami taste**, which was first identified and named by a Japanese researcher, is triggered by amino acids, especially glutamate. The presence of amino acids, as found in meat for example, serves as a marker for a desirable, nutritionally protein-rich food. Glutamate binds to a G protein-coupled receptor and activates a second-messenger system, but the details of this pathway are unknown. In addition to giving us our sense of meaty flavours, this pathway is responsible for the distinctive taste of the flavour additive monosodium glutamate (MSG), which is especially popular in Asian dishes.

Taste perception is also influenced by information derived from other receptors, especially smell (odour). When you temporarily lose your sense of smell because of

swollen nasal passageways during a cold, your sense of taste is also markedly reduced, even though your taste receptors are unaffected by the cold. Other factors affecting taste include temperature and texture of the food as well as psychological factors associated with past experiences with the food. How the cortex accomplishes the complex perceptual processing of taste sensation is currently not known.

Olfactory receptors in the nose

The **olfactory mucosa** (smell), a 3 cm^2 patch of mucosa in the ceiling of the nasal cavity, contains three cell types: *olfactory receptor cells*, *supporting cells*, and *basal cells* (► Figure 4-38). The supporting cells secrete mucus, which coats the nasal passages. The basal cells are precursors for new olfactory receptor cells, which are replaced about every two months. An **olfactory receptor cell** is an afferent neuron whose receptor portion lies in the olfactory mucosa in the nose and whose afferent axon traverses into the brain. The axons of the olfactory receptor cells collectively form the **olfactory nerve**.

The receptor portion of an olfactory receptor cell consists of an enlarged knob bearing several long cilia that extend like a tassel to the surface of the mucosa. These cilia contain the binding sites for attachment of **odourants**, which are molecules that can be smelled. During quiet breathing, odourants typically reach the sensitive receptors only by diffusion, because the olfactory mucosa is above the normal path of airflow. The act of sniffing enhances this process by drawing the air currents upward within the nasal cavity so that a greater percentage of the odoriferous molecules in the air come into contact with the olfactory mucosa. Odourants also reach the olfactory mucosa during eating by wafting up to the nose from the mouth through the pharynx (back of the throat).

FIGURE 4-38 Location and structure of the olfactory receptors

To be smelled, a substance must be (1) sufficiently volatile (easily vaporized) that some of its molecules can enter the nose in the inspired air, and (2) sufficiently water soluble that it can dissolve in the mucus that coats the olfactory mucosa. As with taste receptors, to be detected by olfactory receptors, molecules must be dissolved.

Detecting and sorting odour components

The human nose contains 5 million olfactory receptors, of which there are 1000 different types. During smell detection, an odour is “dissected” into various components. Each receptor responds to only one discrete component of an odour rather than to the whole odourant molecule. Accordingly, each of the various parts of an odour is detected by one of the thousand different receptors, and a given receptor can respond to a particular odour component shared in common by different scents. Compare this to the three cone types for coding colour vision and to the taste buds that respond differentially to only five primary tastes to accomplish coding for taste discrimination.

Binding of an appropriate scent signal to an olfactory receptor activates a G protein, triggering a cascade of cAMP-dependent intracellular reactions that leads to opening of Na^+ channels. The resultant ion movement brings about a depolarizing receptor potential that generates action potentials in the afferent fibre. The frequency of the action potentials depends on the concentration of the stimulating chemical molecules.

The afferent fibres arising from the receptor endings in the nose pass through tiny holes in the flat bone plate separating the olfactory mucosa from the overlying brain tissue

(Figure 4-38). They immediately synapse in the **olfactory bulb**, a complex neural structure containing several different layers of cells that are functionally similar to the retinal layers of the eye. The twin olfactory bulbs, one on each side, are about the size of small grapes. Each olfactory bulb is lined by small ball-like neural junctions known as **glomeruli** (little balls) (Figure 4-39). Within each glomerulus, the terminals of receptor cells carrying information about a particular scent component synapse with the next cells in the olfactory pathway, the **mitral cells**. Because each glomerulus receives signals only from receptors that detect a particular odour component, the glomeruli serve as “smell files.” The separate components of an odour are sorted into different glomeruli, one component per file. Thus, the glomeruli, which serve as the first relay station in the brain for processing olfactory information, play a key role in organizing scent perception.

The mitral cells on which the olfactory receptors terminate in the glomeruli refine the smell signals and relay them to the brain for further processing. Fibres leaving the olfactory bulb travel in two different routes:

- A subcortical route going primarily to regions of the limbic system, especially the lower medial sides of the temporal lobes (considered the **primary olfactory cortex**). This route, which includes hypothalamic involvement, permits close coordination between smell and behavioural reactions associated with feeding, mating, and direction orienting.
- A route through the thalamus to the cortex. As with other senses, the cortical route is important for the perception and fine discrimination of smell.

► **FIGURE 4-39 Processing of scents in the olfactory bulb.** Each of the glomeruli lining the olfactory bulb receives synaptic input from only one type of olfactory receptor, which, in turn, responds to only one discrete component of an odourant. Thus, the glomeruli sort and file the various components of an odoriferous molecule before relaying the smell signal to the mitral cells and higher brain levels for further processing.

Odour discrimination

Because each odourant activates multiple receptors and glomeruli in response to its various odour components, odour discrimination is based on different patterns of glomeruli activation achieved by various scents. In this way, the cortex can distinguish more than 10 000 different scents. This mechanism for sorting out and distinguishing different odours is very effective. A noteworthy example is our ability to detect methyl mercaptan (garlic odour) at a concentration of 1 molecule per 50 billion molecules in the air! This substance is added to odourless natural gas to enable us to detect potentially lethal gas leaks. Despite this impressive sensitivity, humans have a poor sense of smell compared with other species. By comparison, a dog's sense of smell is hundreds of times more sensitive than that of a human. Bloodhounds, for example, have about 4 billion olfactory receptor cells, compared with our 5 million such cells, accounting for their superior scent-sniffing ability.

Adaptability of the olfactory system

Although the olfactory system is sensitive and highly discriminating, it is also quickly adaptive. Sensitivity to a new odour

diminishes rapidly after a short period of exposure to it, even though the odour source continues to be present. This reduced sensitivity does not involve receptor adaptation, as researchers thought for years; actually, the olfactory receptors themselves adapt slowly. It apparently involves some sort of adaptation process in the CNS. Adaptation is specific for a particular odour, and responsiveness to other odours remains unchanged.

What clears the odourants away from their binding sites on the olfactory receptors so that the sensation of smell doesn't linger after the source of the odour is removed? Several "odour-eating" enzymes recently discovered in the olfactory mucosa serve as molecular janitors, clearing away the odoriferous molecules so that they do not continue to stimulate the olfactory receptors. Interestingly, these odourant-clearing enzymes are very similar chemically to detoxification enzymes found in the liver. (These liver enzymes inactivate potential toxins absorbed from the digestive tract; p. 671) This resemblance may not be coincidental. Researchers speculate that the nasal enzymes may serve the dual purpose of clearing the olfactory mucosa of old odourants and transforming potentially harmful chemicals into harmless molecules. Such detoxification would serve a very useful purpose, considering the open passageway between the olfactory mucosa and the brain.

The vomeronasal organ

In addition to the olfactory mucosa, the nose contains another sense organ, the **vomeronasal organ (VNO)**, which is common in other mammals but until recently was thought nonexistent in humans. The VNO is located about 15 mm inside the human nose next to the vomer bone—hence, its name. It detects **pheromones**, nonvolatile chemical signals passed subconsciously from one individual to another. In animals, binding of a pheromone to its receptor on the surface of a neuron in the VNO triggers an action potential that travels through nonolfactory pathways to the limbic system, the brain region that governs emotional responses and sociosexual behaviours. These signals never reach the higher levels of conscious awareness. In animals, the VNO is known as the "sexual nose" for its role in governing reproductive and social behaviours, such as identifying and attracting a mate and communicating social status.

Some scientists now claim the existence of pheromones in humans, although many skeptics doubt these findings. Although the role of the VNO in human behaviour has not been validated, some researchers suspect that it is responsible for spontaneous "feelings" between people, either "good chemistry," such as "love at first sight," or "bad chemistry," such as "getting bad vibes"

from someone you just met. They speculate that pheromones in humans subtly influence sexual activity, compatibility with others, or group behaviour, similar to the role they play in other mammals, although this messenger system is nowhere as powerful or important in humans as in animals. Because messages conveyed by the VNO seem to bypass cortical consciousness, the response to the largely odourless pheromones is not a distinct, discrete perception, such as smelling a favourite fragrance, but more like an inexplicable impression.

This completes our discussion of the afferent nervous system, which is responsible for sensing (via receptors) and transmitting information from the periphery to the CNS (spinal cord and higher brain centres). We now address the transmission of information from the CNS to the periphery (e.g., skeletal muscle, heart, lungs). The information transmitted is used to effect change, for example, increasing or decreasing heart rate.

Check Your Understanding 4.5

1. List the five established primary tastes and the stimuli that evoke each of these taste sensations.
2. Describe how odour discrimination is accomplished.

4.8 | The Peripheral Nervous System: Efferent Division

Once the afferent division of the PNS communicates with the CNS, the efferent division then communicates with the effector organs (muscles and glands) to carry out the intended effects. Therefore, the action potential flow is in the opposite direction to that of the afferent neuron.

The efferent nerves, known as motor or effector neurons, carry nerve action potentials away from the CNS to muscles and glands and other structures (e.g., cells of the inner ear). Structurally, the cell body, oval in shape, of the efferent neuron is connected to a single, long axon and several shorter dendritic projections from the cell body. This axon then forms a neuronal junction with the effector. The efferent neuron is present in the grey matter of the spinal cord and medulla oblongata.

Only two neurotransmitters are used by effector neurons: acetylcholine and norepinephrine. These neurotransmitters bring about diverse effects such as salivary secretion, bladder contraction, and voluntary motor movements. These effects are a prime example of how the same chemical messenger may elicit a multiplicity of responses from various tissues, depending on the specialization of the effector organs.

Cardiac muscle, smooth muscle, most exocrine glands, some endocrine glands, and adipose tissue (fat) are innervated by the autonomic nervous system (ANS), the involuntary branch of the peripheral efferent division. Skeletal muscle is innervated by the somatic nervous system, the branch of the efferent division subject to voluntary control. Efferent output typically influences

either movement (e.g., walking) or secretion (e.g., catecholamines). We examine these two branches of the efferent division of the PNS in Sections 4.9 and 4.10.

Much of the efferent output is directed toward maintaining homeostasis, but it is also important in responding to stresses, such as the fight-or-flight response. Let's revisit the example of fight-or-flight response introduced at the beginning of this chapter and, in doing so, outline the contributions of the efferent division of the PNS.

Fight-or-flight response

The fight-or-flight example asked you to envision walking in the woods and hearing a rustling of leaves and branches behind you; you stop to look and see a bear. Do you run, back up slowly, or confront the bear by making yourself as threatening as possible? During this acutely stressful situation, unnecessary functions are reduced, and energy is diverted to other functions vital to survival. Some of the physiological adjustments to stress are as follows (for further discussion, see Times of Sympathetic Dominance, p. 191):

- The cardiorespiratory system responds by increasing heart rate, blood pressure, and rate and depth of respiration.
- Energy stores are mobilized for use by working tissues, for example, skeletal muscles.
- Redistribution of resources (via vasodilation and vasoconstriction) takes place, which is based on priority need. Blood flow and oxygen delivery to the digestive tract is constricted, and saliva production in the mouth is reduced, as these are nonessential at this time. In contrast, blood flow and oxygen delivery is increased to skeletal muscles, heart, lungs, and skin.
- Secretion of epinephrine, norepinephrine, and other hormones is increased, which assist in accelerating heart rate, mobilizing energy, and if necessary, reducing pain.

Now let's look at a general overview of the autonomic nervous system (ANS).

4.9 | Autonomic Nervous System

The ANS influences smooth muscles, glands, and the heart through its two subdivisions: the sympathetic and the parasympathetic systems. These subdivisions maintain a dynamic equilibrium aimed at maintenance of homeostasis. The ANS also includes the enteric nervous system that functions within the gastrointestinal tract and influences the pancreas, liver, and gallbladder, thereby controlling gastrointestinal motility, secretion, and blood flow. The hypothalamus, brain stem, and spinal cord are the hub of the neural output of the ANS. The motor and premotor cortex and the hypothalamus adjust much of the output from the ANS. These central regulators of the ANS also adjust the secretion of hormones that influence blood volume and total peripheral resistance.

The cerebral cortex incorporates all inputs of sight, smell, hearing, and equilibrium, as well as somatosensory information (e.g., touch and pain). The integration of these inputs into an appropriate response takes place largely in the hypothalamus and medulla. The efferent signals are sent to the periphery via the sympathetic and parasympathetic pathways. The central regulators of the ANS also coordinate the stress response (e.g., fight-or-flight response), reproduction, and thermoregulation.

Autonomic nerve pathways

Each autonomic nerve pathway extending from the CNS to an innervated organ is a two-neuron chain (► Figure 4-40). The cell body of the first neuron in the series is located in the CNS. Its axon, the **preganglionic fibre**, synapses with the cell body of the second neuron, which lies within a ganglion. (Recall that a ganglion is a cluster of neuronal cell bodies outside the CNS.) The axon of the second neuron, the **postganglionic fibre**, innervates the effector organ (smooth muscle, heart).

The ANS has two subdivisions—the sympathetic nervous system and the parasympathetic nervous systems (► Figure 4-41). Sympathetic nerve fibres originate in the thoracic and lumbar regions of the spinal cord (p. 102). Most sympathetic preganglionic fibres are very short; they synapse with cell bodies of postganglionic neurons within ganglia that lie in a **sympathetic ganglion chain** (also called the **sympathetic trunk**) located along either side of the spinal cord (see Figure 3-24). Long postganglionic fibres originating in the ganglion chain end on the effector organs. Some preganglionic fibres pass through the ganglion chain without synapsing. Instead, they end later in sympathetic **collateral ganglia** about halfway between the CNS and the innervated organs, and postganglionic fibres travel the rest of the distance.

Parasympathetic preganglionic fibres arise from the cranial (brain) and sacral (lower spinal cord) areas of the CNS. These fibres are longer than sympathetic preganglionic fibres because they do not end until they reach **terminal ganglia** that lie in or near the effector organs. Very short postganglionic fibres end on the cells of an organ itself.

Parasympathetic and sympathetic postganglionic fibres

Sympathetic and parasympathetic preganglionic fibres release the same neurotransmitter, **acetylcholine (ACh)**, but the postganglionic endings of these two systems release different neurotransmitters (the neurotransmitters that influence the effector organs). Parasympathetic postganglionic fibres release acetylcholine. Accordingly, they, along with all autonomic preganglionic fibres, are called **cholinergic fibres**. Most sympathetic postganglionic fibres, in contrast, are called **adrenergic fibres** because they release **noradrenaline**, commonly known as **norepinephrine**.¹ Both acetylcholine and norepinephrine also serve as chemical messengers elsewhere in the body (► Table 4-7).

Postganglionic autonomic fibres do not end in a single terminal swelling like a synaptic knob. Instead, the terminal branches of autonomic fibres have numerous swellings, or **varicosities**, that simultaneously release neurotransmitter over a large area of the innervated organ rather than on single cells (see ► Figure 4-40, and Figure 7-29). This diffuse release of neurotransmitter, coupled with the fact that any resulting change in electrical activity is spread throughout a smooth or cardiac muscle mass via gap junctions (p. 35), means that autonomic activity typically influences whole organs instead of discrete cells.

Innervations of visceral organs

Afferent information coming from the viscera (internal organs) usually does not reach the conscious level. Likewise, visceral activities, such as circulation, digestion, sweating, and pupillary size, are regulated outside the realm of consciousness and voluntary control via autonomic efferent output. Most visceral organs are innervated by both sympathetic and parasympathetic nerve fibres (► Figure 4-42). ► Table 4-8 summarizes the major effects of these autonomic branches. Although the details of this wide array of autonomic responses are described more fully in the later chapters that discuss the individual organs involved, you can consider several general concepts now. As you can see from Table 4.8, the sympathetic and parasympathetic nervous systems generally exert opposite effects in a particular organ.

► FIGURE 4-40 Autonomic nerve pathway

► **FIGURE 4-41 Autonomic nervous system.** The sympathetic nervous system, which originates in the thoracolumbar regions of the spinal cord, has short cholinergic (acetylcholine-releasing) preganglionic fibres and long adrenergic (norepinephrine-releasing) postganglionic fibres. The parasympathetic nervous system, which originates in the brain and sacral region of the spinal cord, has long cholinergic preganglionic fibres and short cholinergic postganglionic fibres. In most instances, sympathetic and parasympathetic postganglionic fibres both innervate the same effector organs. The adrenal medulla is a modified sympathetic ganglion, which releases epinephrine and norepinephrine into the blood.

For example, sympathetic stimulation increases the heart rate, whereas parasympathetic stimulation decreases it; sympathetic stimulation slows down movement within the digestive tract, whereas parasympathetic stimulation enhances digestive motility. Note that both systems increase the activity of some organs and reduce the activity of others.

Rather than memorize a list, such as that in Table 4-8, it is better to logically deduce the actions of the two systems by first understanding the circumstances under which each system dominates. Usually both systems are partially active; that is, normally some level of action potential activity exists in both the sympathetic and the parasympathetic fibres supplying a particular organ. This ongoing activity is called **sympathetic or parasympathetic tone**, or tonic activity. Under specific circumstances, the activity of one ANS subdivision can dominate the other. *Sympathetic dominance* to a particular organ exists when the sympathetic fibres' rate of firing to that organ increases above tonic level, coupled with a simultaneous decrease below tonic level in the parasympathetic fibres' frequency of action potentials to the same organ. The reverse situation is true for *parasympathetic dominance*. The balance between sympathetic and parasympathetic activity can be shifted

■ **TABLE 4-7 Sites of Release for Acetylcholine and Norepinephrine**

Acetylcholine	Norepinephrine
All preganglionic terminals of the autonomic nervous system	Most sympathetic postganglionic terminals
All parasympathetic postganglionic terminals	Adrenal medulla
Sympathetic postganglionic terminals at sweat glands and some blood vessels in skeletal muscle	Central nervous system
Terminals of efferent neurons supplying skeletal muscle (motor neurons)	Central nervous system

► **FIGURE 4-42** Schematic representation of the structures innervated by the sympathetic and parasympathetic nervous systems

in two ways: (1) separately for individual organs to meet specific demands (e.g., sympathetically induced dilation of the pupil in dim light; p. 154–155) and (2) by a more generalized, widespread discharge of one autonomic system in favour of the other to control

body-wide functions. Such massive, widespread discharges take place more frequently in the sympathetic system. The value of massive sympathetic discharge is clear, considering the circumstances during which this system usually dominates.

■ **TABLE 4-8** Effects of Autonomic Nervous System on Various Organs

Organ	Effect of Sympathetic Stimulation	Effect of Parasympathetic Stimulation
Heart	Increased rate, increased force of contraction (of whole heart)	Decreased rate, decreased force of contraction (of atria only)
Blood Vessels	Constriction	Dilation of vessels supplying the penis and clitoris only
Lungs	Dilation of bronchioles (airways) Inhibition of mucous secretion	Constriction of bronchioles Stimulation of mucous secretion
Digestive Tract	Decreased motility (movement) Contraction of sphincters (to prevent forward movement of contents) Inhibition of digestive secretions	Increased motility Relaxation of sphincters (to permit forward movement of contents) Stimulation of digestive secretions
Urinary Bladder	Relaxation	Contraction (emptying)
Eye	Dilation of pupil Adjustment of eye for far vision	Constriction of pupil Adjustment of eye for near vision
Liver (glycogen stores)	Glycogenolysis (glucose released)	None
Adipose Cells (fat stores)	Lipolysis (fatty acids released)	None
Exocrine Glands		
<i>Exocrine pancreas</i>	Inhibition of pancreatic exocrine secretion	Stimulation of pancreatic exocrine secretion (important for digestion)
<i>Sweat glands</i>	Stimulation of secretion by most sweat glands	Stimulation of secretion by some sweat glands
<i>Salivary glands</i>	Stimulation of small volume of thick saliva rich in mucus	Stimulation of large volume of watery saliva rich in enzymes
Endocrine Glands		
<i>Adrenal medulla</i>	Stimulation of epinephrine and norepinephrine secretion	None
<i>Endocrine pancreas</i>	Inhibition of insulin secretion; stimulation of glucagon secretion	Stimulation of insulin and glucagon secretion
Genitals	Ejaculation and orgasmic contractions (males); orgasmic contractions (females)	Erection (caused by dilation of blood vessels in penis [male] and clitoris [female])
Brain Activity	Increased alertness	None

TIMES OF SYMPATHETIC DOMINANCE

The sympathetic nervous system promotes responses that prepare the body for strenuous physical activity in emergency or stressful situations, such as a physical threat from the environment. This response is typically referred to as a **fight-or-flight response**, because the sympathetic nervous system readies the body to fight against or flee from the threat (as in the chapter opening example of encountering a bear). Think about the body

resources needed in such circumstances. The sympathetic outflow (from the hypothalamus, brain stem, spinal cord) to the heart increases heart rate and force of myocardial contraction (contractility), and global vasoconstriction (narrowing of blood vessels) occurs, both of which increase mean arterial and systolic blood pressure. Respiratory airways dilate (open wide) to permit increased ventilation (airflow); energy stores (i.e., carbohydrate and fat) are mobilized and broken down to release additional fuel

into the blood for use by active tissues (e.g., skeletal muscle); and local vasodilation occurs in skeletal muscles to supply the additional oxygen and carbohydrates, and to remove by-products (e.g., hydrogen ions). All these responses are aimed at providing an increase in oxygen and nutrient availability via the blood to the active tissues (e.g., heart, lungs, skeletal muscles, and brain) in anticipation of strenuous physical activity. And because digestion and urination are not essential functions at this time, the sympathetic nervous system inhibits them, saving the additional blood flow for the active tissue. Sweating is promoted in anticipation of excess heat production by the physical exertion. Furthermore, vision and hearing are heightened to allow the person to accurately assess the entire threatening scene.

TIMES OF PARASYMPATHETIC DOMINANCE

In quiet and restful circumstances, the parasympathetic system dominates, allowing the body to focus on its own “general housekeeping” activities (e.g., digestion). The parasympathetic system promotes these “**rest-and-digest**” types of bodily functions while slowing down those activities that are enhanced by the sympathetic system. There is no need, for example, to have the heart beating rapidly and forcefully when the person is in a tranquil setting.

ADVANTAGE OF DUAL AUTONOMIC INNERVATION

The dual control exerted by the ANS provides more precise control, similar to the accelerator-and-brake system in an automobile. This type of dual control mechanism is termed **antagonistic**, while the unopposed sympathetic on-off control of vasoconstriction is termed **tonic**. If an animal suddenly darts across the road as you are driving, you could eventually stop if you just take your foot off the accelerator (tonic control), but you might stop too slowly to avoid hitting the animal. If you simultaneously apply the brake as you lift up on the accelerator (antagonistic control), however, you can come to a more rapid, controlled stop. In a similar manner, a sympathetically accelerated heart rate could gradually be reduced to normal following a stressful situation by decreasing the firing rate in the cardiac sympathetic nerve (letting up on the accelerator). However, the heart rate can be reduced more rapidly by simultaneously increasing activity in the parasympathetic supply to the heart (applying the brake). Indeed, the two divisions of the ANS are usually reciprocally controlled; increased activity in one division is accompanied by a corresponding decrease in the other.

There are several exceptions to the general rule of dual reciprocal innervations by the two branches of the ANS; the most notable are the following:

- *Innervated blood vessels* (most arterioles and veins are innervated; arteries and capillaries are not) receive only sympathetic nerve fibres. Regulation is accomplished by increasing or decreasing the firing rate above or below the tonic level in these sympathetic fibres. The only blood vessels to receive both sympathetic and parasympathetic fibres are those supplying the penis and clitoris. The precise vascular control this dual innervation affords these organs is important in accomplishing erection.

- Most *sweat glands* are innervated only by sympathetic nerves. The postganglionic fibres of these nerves are unusual because they secrete acetylcholine rather than norepinephrine.
- *Salivary glands* are innervated by both autonomic divisions, but, unlike elsewhere, sympathetic and parasympathetic activity is not antagonistic. Both stimulate salivary secretion, but the saliva's volume and composition differ, depending on which autonomic branch is dominant.

You will learn more about these exceptions in later chapters. We are now going to turn our attention to the adrenal medulla, a unique endocrine component of the sympathetic nervous system.

The adrenal medulla

There are two *adrenal glands*, one lying above the kidney on each side. The adrenal glands are endocrine glands, each with an outer portion, the *adrenal cortex*, and an inner portion, the *adrenal medulla*. The **adrenal medulla** is a modified sympathetic ganglion that does not give rise to postganglionic fibres. Instead, on stimulation by the preganglionic fibre that originates in the CNS, it secretes hormones into the blood (► Figure 4-43; also see ► Figure 4-41). Not surprisingly, the hormones are identical or similar to postganglionic sympathetic neurotransmitters. About 20 percent of the adrenal medullary hormone output is norepinephrine, and the remaining 80 percent is the closely related substance **epinephrine (adrenaline)**. These hormones, in general, reinforce activity of the sympathetic nervous system.

Different receptor types

Because each autonomic neurotransmitter and medullary hormone stimulates activity in some tissues but inhibits activity in others, the particular responses must depend on specialization of the tissue cells rather than on properties of the chemicals themselves. Responsive tissue cells have one or more of several different types of plasma membrane receptor proteins for these chemical messengers. Binding of a neurotransmitter to a receptor induces the tissue-specific response.

CHOLINERGIC RECEPTORS

Researchers have identified two types of acetylcholine (cholinergic) receptors—*nicotinic* and *muscarinic receptors*—on the basis of their response to particular drugs. **Nicotinic receptors** are activated by the tobacco plant derivative nicotine, whereas **muscarinic receptors** are activated by the mushroom poison muscarine.

Nicotinic receptors are found on the postganglionic cell bodies in all autonomic ganglia. These receptors respond to acetylcholine released from both sympathetic and parasympathetic preganglionic fibres. Binding of acetylcholine to these receptors brings about the opening of cation channels in the postganglionic cell, which permits passage of both Na^+ and K^+ . Because of the greater electrochemical gradient for Na^+ than for K^+ , more Na^+ enters the cell than K^+ leaves, bringing about a

FIGURE 4-43 Comparison of the release and binding to receptors of epinephrine and norepinephrine. Norepinephrine is released both as a neurotransmitter from sympathetic postganglionic fibres and as a hormone from the adrenal medulla. Beta-1 (β_1) receptors bind equally with both norepinephrine and epinephrine, whereas beta-2 (β_2) receptors bind primarily with epinephrine. Alpha (α) receptors of both subtypes have a greater affinity for norepinephrine than for epinephrine.

depolarization that leads to initiation of an action potential in the postganglionic cell.

Muscarinic receptors are found on effector cell membranes (smooth muscle, cardiac muscle, and glands). They bind with acetylcholine released from parasympathetic postganglionic fibres. There are five subtypes of muscarinic receptors, all of which are linked to G proteins that activate second-messenger systems that lead to the target cell response.

ADRENERGIC RECEPTORS

There are two primary classifications of adrenergic receptors for epinephrine and norepinephrine (catecholamine receptors): alpha (α) and beta (β) receptors. The α and β receptors are further subclassified as α_1 and α_2 , and β_1 , β_2 , and β_3 . Catecholamine receptors act through secondary messengers to transfer the signal from the cell surface into the cytoplasm, in order to influence metabolic processes and thus cellular function. These various receptor types are distinctly distributed among the

effector organs. Receptors of the β_2 type bind primarily with epinephrine, whereas β_1 receptors have about equal affinities for norepinephrine and epinephrine, and α receptors of both subtypes have a greater sensitivity to norepinephrine than to epinephrine (Figure 4-43).

All adrenergic receptors are coupled to G proteins, but the ensuing pathway differs for the various receptor types, which can have either stimulatory or inhibitory influences. Activation of both β_1 and β_2 receptors brings about the target cell response by means of the cyclic AMP second-messenger system (p. 217). Stimulation of α_1 receptors elicits the desired response via the Ca^{2+} second-messenger system (p. 218). By contrast, binding of a neurotransmitter to an α_2 receptor blocks cyclic AMP production in the target cell.

Activation of α_1 receptors usually brings about an excitatory response in the effector organ—for example, arteriolar constriction caused by increased contraction of smooth muscle in the walls of these blood vessels. The α_1 receptors are present in most sympathetic target tissues. Activation of α_2 receptors, in contrast, brings about an inhibitory response in the effector organ, such as decreased smooth muscle contraction in the digestive tract.

Stimulation of β_1 receptors, which are found primarily in the heart, causes an excitatory response, namely, increased rate and force of cardiac contraction. The response to β_2 receptor activation is generally inhibitory, such as arteriolar or bronchiolar (respiratory airway) dilation caused by relaxation of the smooth muscle in the walls of these tubular structures. Salbutamol is a short-lived bronchodilator that acts through the β_2 -adrenergic receptor to provide relief from bronchospasm, but it also has implications for aerobic sports as an ergogenic aid. Salbutamol's function as an ergogenic aid is currently under investigation by researchers B. Sporer and D. MacKenzie at the University of British Columbia. While β_1 and β_2 receptors are more commonly found within the body, β_3 is less common. An example of a tissue associated with the β_3 receptor is adipose tissue (i.e., fat cells). The sympathetic nervous system stimulates adipose tissue to break down fat molecules via both the β_3 and α_2 receptors.

AUTONOMIC AGONISTS AND ANTAGONISTS

Drugs are available that selectively alter autonomic responses at each of the receptor types. **Agonists** bind to the same receptor as the neurotransmitter and elicit an effect that mimics that of the transmitter. **Antagonists**, by contrast, bind with the receptor and block the neurotransmitter's response. Some of these drugs are only of experimental interest, but others are very important therapeutically. For example, *atropine* blocks the effect of acetylcholine at muscarinic receptors, but does not affect nicotinic receptors. Because acetylcholine released at both parasympathetic and sympathetic preganglionic fibres combines with nicotinic receptors, blockage at nicotinic synapses would knock out both these autonomic branches. By acting selectively to interfere with acetylcholine action only at muscarinic junctions—the sites of parasympathetic postganglionic action—atropine effectively blocks parasympathetic effects but does not influence sympathetic activity at all. Doctors use this principle to suppress salivary and bronchial secretions before surgery, to reduce the risk of a patient inhaling these secretions into the lungs.

Likewise, there are widely used drugs that act selectively at α - and β -adrenergic receptor sites to either activate or block specific sympathetic effects. *Salbutamol* is an excellent example. It selectively activates β_2 -adrenergic receptors at low doses, making it possible to dilate the bronchioles in the treatment of asthma without undesirably stimulating the heart (the heart has mostly β_1 receptors).

Control of autonomic activities

Messages from the CNS are delivered to cardiac muscle, smooth muscle, and glands via the autonomic nerves, but which regions of the CNS regulate autonomic output? The following summarizes these regions and their regulatory functions:

- The spinal cord integrates some autonomic reflexes, such as urination, defecation, and erection, but all these spinal reflexes are subject to control by higher levels of consciousness.
- The medulla within the brain stem is most directly responsible for autonomic output, and includes centres for controlling cardiovascular, respiratory, and digestive activity via the autonomic system.
- The hypothalamus plays an important role in integrating the autonomic, somatic, and endocrine responses that automatically accompany various emotional and behavioural states. For example, the increased heart rate, blood pressure, and respiratory activity associated with anger or fear are brought about by the hypothalamus acting through the medulla.
- The prefrontal association cortex can also influence autonomic output through its involvement with emotional expression characteristic of the individual's personality. An example is blushing when embarrassed, which is caused by dilation of

blood vessels supplying the skin of the cheeks. Such responses are mediated through hypothalamic-medullary pathways.

■ Table 4-9 summarizes the main distinguishing features of the sympathetic and parasympathetic nervous systems.

4.10 | Somatic Nervous System
Motor neurons and skeletal muscle

Skeletal muscle is innervated by **motor neurons**, the axons of which constitute the somatic nervous system. The cell bodies of almost all motor neurons are within the ventral horn of the spinal cord; the only exception is that the cell bodies of motor neurons supplying muscles in the head are in the brain stem. Unlike the two-neuron chain of autonomic nerve fibres, the axon of a motor neuron is continuous from its origin in the CNS to its ending on skeletal muscle. Motor neuron axon terminals release acetylcholine, which brings about excitation and contraction of

■ TABLE 4-9 Distinguishing Features of Sympathetic Nervous System and Parasympathetic Nervous System

Feature	Sympathetic System	Parasympathetic System
Origin of Preganglionic Fibre	Thoracic and lumbar regions of spinal cord	Brain and sacral region of spinal cord
Origin of Postganglionic Fibre (location of ganglion)	Sympathetic ganglion chain (near spinal cord) or collateral ganglia (about halfway between spinal cord and effector organs)	Terminal ganglia (in or near effector organs)
Length and Type of Fibre	Short cholinergic preganglionic fibres	Long cholinergic preganglionic fibres
	Long adrenergic postganglionic fibres	Short cholinergic postganglionic fibres
Effector Organs Innervated	Cardiac muscle, almost all smooth muscle, most exocrine glands, and some endocrine glands	Cardiac muscle, most smooth muscle, most exocrine glands, and some endocrine glands
Types of Receptors for Neurotransmitters	For preganglionic neurotransmitter: nicotinic	For preganglionic neurotransmitter: nicotinic
	For postganglionic neurotransmitter: α_1 , α_2 , β_1 , β_2	For postganglionic neurotransmitter: muscarinic
Dominance	Dominates in emergency fight-or-flight situations; prepares body for strenuous physical activity	Dominates in quiet, relaxed situations; promotes "general housekeeping" activities, such as digestion

the innervated muscle cells. Motor neurons can only stimulate skeletal muscle, and not inhibit it, unlike the autonomic fibres and their effector organs. Inhibition of skeletal muscle activity can be accomplished only within the CNS through inhibitory synaptic input to the dendrites and cell bodies of the motor neurons supplying that particular muscle.

Motor neurons: The final common pathway

Motor neuron dendrites and cell bodies are influenced by many converging presynaptic inputs, both excitatory and inhibitory. Some of these inputs are part of spinal reflex pathways originating with peripheral sensory receptors. Others are part of descending pathways originating within the brain. Areas of the brain that exert control over skeletal muscle movements include the motor regions of the cortex, the basal nuclei, the cerebellum, and the brain stem; see Figure 7-22 for a summary of motor control, and Figure 3-28b, for specific examples of these descending motor pathways).

Motor neurons are considered the **final common pathway**, because the only way any other parts of the nervous system can influence skeletal muscle activity is by acting on these motor neurons. The level of activity in a motor neuron and its subsequent output to the skeletal muscle fibres it innervates depend on the relative balance of EPSPs and IPSPs (pp. 76) brought about by its presynaptic inputs originating from these diverse sites in the brain.

The somatic system is under voluntary control, but much of the skeletal muscle activity involving posture, balance, and stereotypical movements is subconsciously controlled. You may decide you want to start walking, but you do not have to consciously bring about the alternate contraction and relaxation of the involved muscles because these movements are involuntarily coordinated by lower brain centres.

The cell bodies of the crucial motor neurons may be selectively destroyed by **poliovirus**. The result is paralysis of the muscles innervated by the affected neurons. **Amyotrophic lateral sclerosis (ALS)**, also known as **Lou Gehrig's disease**, is the most common motor-neuron disease. ALS is associated with pathological changes in (1) neurofilaments that block axonal transport of crucial materials, (2) extracellular accumulation of toxic levels of the excitatory neurotransmitter glutamate, (3) aggregation of misfolded intracellular proteins, or (4) mitochondrial dysfunction leading to reduced energy production.

Before turning our attention to the junction between a motor neuron and the muscle cells it innervates, we are going to pull together in tabular form two groups of information we have been examining. ■ Table 4-10 summarizes the features of the two branches of the efferent division of the peripheral nervous system—the ANS and the somatic nervous system. ■ Table 4-11 compares the three functional types of neurons—afferent neurons, efferent neurons, and interneurons.

■ **TABLE 4-10** Comparison of the Autonomic Nervous System and the Somatic Nervous System

Feature	Autonomic Nervous System	Somatic Nervous System
Site of Origin	Brain or lateral horn of spinal cord	Ventral horn of spinal cord for most; those supplying muscles in head originate in brain
Number of Neurons from Origin in CNS to Effector Organ	Two-neuron chain (preganglionic and postganglionic)	Single neuron (motor neuron)
Organs Innervated	Cardiac muscle, smooth muscle, exocrine and some endocrine glands	Skeletal muscle
Type of Innervation	Most effector organs dually innervated by the two antagonistic branches of this system (sympathetic and parasympathetic)	Effector organs innervated only by motor neurons
Neurotransmitter at Effector Organs	May be acetylcholine (parasympathetic terminals) or norepinephrine (sympathetic terminals)	Only acetylcholine
Effects on Effector Organs	Either stimulation or inhibition (antagonistic actions of two branches)	Stimulation only (inhibition possible only centrally through IPSPs on dendrites and cell body of motor neuron)
Types of Control	Under involuntary control	Subject to voluntary control; much activity subconsciously coordinated
Higher Centres Involved in Control	Spinal cord, medulla, hypothalamus, prefrontal association cortex	Spinal cord, motor cortex, basal nuclei, cerebellum, brain stem

■ **TABLE 4-11** Comparison of Types of Neurons

Feature	Afferent Neuron	Efferent Neuron		
		Autonomic Nervous System	Somatic Nervous System	Interneuron
Origin, Structure, Location	Receptor at peripheral ending; elongated peripheral axon, which travels in peripheral nerve; cell body located in dorsal root ganglion; short central axon entering spinal cord	Two-neuron chain; first neuron (preganglionic fibre) originating in CNS and terminating within a ganglion; second neuron (postganglionic fibre) originating in the ganglion and terminating on the effector organ	Cell body of motor neuron lying in spinal cord; long axon travelling in peripheral nerve and terminating on the effector organ	Various shapes; lying entirely within CNS; some cell bodies originating in brain, with long axons travelling down the spinal cord in descending pathways; some originating in spinal cord, with long axons travelling up the cord to the brain in ascending pathways; others forming short local connections
Termination	Interneurons*	Effector organs (cardiac muscle, smooth muscle, exocrine and some endocrine glands)	Effector organs (skeletal muscle)	Other interneurons and efferent neurons
Function	Carries information about the external and internal environment to CNS	Carries instructions from CNS to effector organs	Carries instructions from CNS to effector organs	Processes and integrates afferent input; initiates and coordinates efferent output; responsible for thought and other higher mental functions
Convergence of Input on Cell Body	No (only input is through receptor)	Yes	Yes	Yes
Effect of Input to Neuron	Can only be excited (through receptor potential induced by stimulus; must reach threshold for action potential)	Can be excited or inhibited (through EPSPs and IPSPs at first neuron; must reach threshold for action potential)	Can be excited or inhibited (through EPSPs and IPSPs; must reach threshold for action potential)	Can be excited or inhibited (through EPSPs and IPSPs; must reach threshold for action potential)
Site of Action Potential Initiation	First excitable portion of membrane adjacent to receptor	Axon hillock	Axon hillock	Axon hillock
Divergence of Output	Yes	Yes	Yes	Yes
Effect of Output on Structure on Which It Terminates	Only excites	Postganglionic fibre either excites or inhibits	Only excites	Either excites or inhibits

2. Explain why motor neurons are considered the final common pathway.

4.11 | Neuromuscular Junction

Linkage of motor neurons and skeletal muscle fibres

An action potential in a motor neuron is rapidly propagated from the cell body within the CNS to the skeletal muscle along the large myelinated axon (efferent fibre) of the neuron. As the axon approaches a muscle, it divides into many terminal branches and loses its myelin sheath. Each of these axon terminals forms a special junction, a **neuromuscular junction**,² with one of the many muscle cells (**muscle fibres**) that compose the whole muscle (e.g., biceps muscle) (► Figure 4-44). A single muscle cell is long and cylindrical with bands of light and dark areas. The axon terminal is enlarged into a knoblike structure, the **terminal button**, which fits into a shallow depression, or cleft, in the underlying muscle fibre (► Figure 4-45). Some scientists alternatively call the neuromuscular junction a motor end plate. However, we will reserve the term **motor end plate** for the specialized portion of the muscle cell membrane immediately under the terminal button.

Acetylcholine

Nerve and muscle cells do not actually come into direct contact at a neuromuscular junction. The space (i.e., synaptic cleft) between these two structures is too large to permit electrical transmission of an impulse between them; thus, the action potential cannot jump that far. Furthermore, there are no channels for exit of charge-carrying current from the terminal button. Therefore, just as occurs at a neuronal synapse (p. 75), a chemical messenger carries the signal between the neuron terminal and the muscle fibre. This neurotransmitter is acetylcholine (ACh).

RELEASE OF ACH AT THE NEUROMUSCULAR JUNCTION

Each terminal button contains thousands of vesicles that store ACh. Propagation of an action potential to the axon terminal (► Figure 4-45, step 1) triggers the opening of voltage-gated Ca^{2+} channels in the terminal button (p. 76). Opening of

Ca^{2+} channels permits Ca^{2+} to diffuse into the terminal button down its concentration gradient (step 2), which in turn causes the release of ACh by exocytosis from several hundred vesicles into the cleft (step 3).

FORMATION OF AN END-PLATE POTENTIAL

The released ACh diffuses across the cleft and binds with specific receptor sites, which are specialized membrane proteins unique to the motor end-plate portion of the muscle fibre membrane (step 4). (These cholinergic receptors are of the nicotinic type.) Binding of ACh with these receptor sites induces the opening of chemically gated channels in the motor end plate. These channels permit a small amount of cation traffic through them (both Na^+ and K^+), but no anions (step 5). Because the permeability of the end-plate membrane to Na^+ and K^+ on opening of these channels is essentially equal, the relative movement of these ions through the channels depends on their electrochemical driving forces. Recall that at resting potential, the net driving force for Na^+ is much greater than that for K^+ , because the resting potential is much closer to the K^+ equilibrium potential. Both the concentration and electrical gradients for Na^+ are inward, whereas the outward concentration gradient for K^+ is almost, but not quite, balanced by the opposing inward electrical gradient. As a result, when ACh triggers the opening of these channels, considerably more Na^+ moves inward than K^+ outward, depolarizing the motor end plate. This potential change is called the **end-plate potential (EPP)**. It is a graded potential similar to an EPSP (p. 76), except that an EPP is much larger for the

► **FIGURE 4-44** Motor neuron innervating skeletal muscle cells. When a motor neuron reaches a skeletal muscle, it divides into many terminal branches, each of which forms a neuromuscular junction with a single muscle cell (muscle fibre).

²Many scientists refer to a **synapse** as any junction between two cells that handle information electrically. According to this broad point of view, *chemical synapses* include junctions between two neurons as well as those between a neuron and an effector cell (such as muscle cells of any type or gland cells), and *electrical synapses* include gap junctions between smooth muscle cells or between cardiac muscle cells. We narrowly reserve the term *synapse* specifically for neuron-to-neuron junctions and use different terms for other types of junctions, such as the term *neuromuscular junction* for a junction between a motor neuron and a skeletal muscle cell.

1 An action potential in a motor neuron is propagated to the axon terminal (terminal button).

2 This local action potential triggers the opening of voltage-gated Ca^{2+} channels and the subsequent entry of Ca^{2+} into the terminal button.

3 Ca^{2+} triggers the release of acetylcholine (ACh) by exocytosis from a portion of the vesicles.

4 ACh diffuses across the space separating the nerve and muscle cells and binds with receptor channels specific for it on the motor end plate of the muscle cell membrane.

5 This binding brings about the opening of these nonspecific cation channels, leading to a relatively large movement of Na^{+} into the muscle cell compared to a smaller movement of K^{+} outward.

6 The result is an end-plate potential. Local current flow occurs between the depolarized end plate and the adjacent membrane.

7 This local current flow opens voltage-gated Na^{+} channels in the adjacent membrane.

8 The resultant Na^{+} entry reduces the potential to threshold, initiating an action potential, which is propagated throughout the muscle fibre.

9 ACh is subsequently destroyed by acetylcholinesterase, an enzyme located on the motor end-plate membrane, terminating the muscle cell's response.

© 2016 Cengage

FIGURE 4-45 Events at a neuromuscular junction

following reasons: (1) more neurotransmitter is released from a terminal button than from a presynaptic knob in response to an action potential; (2) the motor end plate has a larger surface area bearing a higher density of neurotransmitter receptor sites, and accordingly, has more sites for binding with neurotransmitter than a subsynaptic membrane has; and (3) many more ion channels are opened in response to the neurotransmitter-receptor complex in the motor end plate. This permits a greater net influx of positive ions and a larger depolarization. As with an

EPSP, an EPP is a graded potential, whose magnitude depends on the amount and duration of ACh at the end plate.

INITIATION OF AN ACTION POTENTIAL

The motor end-plate region itself does not have a threshold potential, so an action potential cannot be initiated at this site. However, an EPP brings about an action potential in the rest of the muscle fibre, as follows. The neuromuscular junction is usually in the middle of the long, cylindrical muscle fibre. When an

EPP takes place, local current flow occurs between the depolarized end plate and the adjacent, resting cell membrane in both directions (step 6), opening voltage-gated Na^+ channels and thus reducing the potential to threshold in the adjacent areas (step 7). The subsequent action potential initiated at these sites propagates throughout the muscle fibre membrane by contiguous conduction (step 8). The spread runs in both directions, away from the motor end plate toward both ends of the muscle fibre, triggering the contraction of the muscle fibre. Thus, by means of ACh, an action potential in a motor neuron brings about an action potential and subsequent contraction in the muscle fibre.

Unlike synaptic transmission, the magnitude of an EPP is normally enough to cause an action potential in the muscle cell. Therefore, one-to-one transmission of an action potential typically occurs at a neuromuscular junction; one action potential in a nerve cell triggers one action potential in a muscle cell that it innervates. Other comparisons of neuromuscular junctions with synapses can be found in ■ Table 4-12.

Acetylcholinesterase and acetylcholine activity

To ensure purposeful movement, a muscle cell's electrical and resultant contractile response to stimulation by its motor neuron must be switched off promptly when there is no longer a signal from the motor neuron. The muscle cell's electrical response is turned off by an enzyme in the motor end-plate membrane; this enzyme is **acetylcholinesterase (AChE)**, which inactivates ACh.

As a result of diffusion, many of the released ACh molecules come into contact with and bind to receptor sites on the surface of the motor end-plate membrane. However, some of the ACh molecules bind with AChE, which is also at the end-plate surface. Being quickly inactivated, this ACh never contributes to the end-plate potential. The acetylcholine that does bind with receptor sites does so very briefly (for about 1 millionth of a second), then detaches. Some of the detached ACh molecules quickly rebind with receptor sites, keeping the end-plate channels open, but some randomly contact AChE instead this time around and are inactivated (Figure 4-45, step 9). As this process repeats, more and more ACh is inactivated until it has been virtually removed from the cleft within a few milliseconds after its release. ACh removal ends the EPP, so the remainder of the muscle cell membrane returns to resting potential. Now the muscle cell can relax. Or, if sustained contraction is essential for the desired movement, another motor neuron action potential leads to the release of more ACh, which keeps the contractile process going. By removing contraction-inducing ACh from the motor end plate, AChE permits the choice of allowing relaxation to take place (no more ACh released) or keeping the contraction going (more ACh released), depending on the body's momentary needs.

■ Clinical Connections

However, she was also experiencing mild muscle weakness, becoming unsteady on her feet, and having problems with fine

So far we have discussed how diabetes has affected Deborah's afferent nerves.

motor control, which prevented her from knitting. Surprisingly, such symptoms are very common in diabetes, yet there is little medical literature to indicate what the exact causes are. Such changes are potentially caused by a combination of damage to motor neurons, damage to motor end plates, and damage to the muscles themselves. Neuropathy due to mechanisms already discussed could account for damaged neurons and motor end plates, but more research is needed. Within the muscles themselves, the weakness can be caused by muscle atrophy—a loss of the muscle mass.

Vulnerability of the neuromuscular junction

Several chemical agents and diseases are known to affect the neuromuscular junction by acting at different sites in the transmission process. Two well-known toxins—*black widow spider venom* and *botulinum toxin*—alter the release of ACh, but do so in opposite directions.

BLACK WIDOW SPIDER VENOM CAUSES EXPLOSIVE RELEASE OF ACH

The venom of black widow spiders exerts its deadly effect by triggering explosive release of ACh from the storage vesicles, not only at neuromuscular junctions but at all cholinergic sites. All cholinergic sites undergo prolonged depolarization, the most harmful result of which is respiratory failure. Breathing is accomplished by alternate contraction and relaxation of skeletal muscles, particularly the diaphragm. Respiratory paralysis occurs as a result of prolonged depolarization of the diaphragm. During this so-called **depolarization block**, the voltage-gated Na^+ channels are trapped in their inactivated state (p. 62), thereby prohibiting the initiation of new action potentials and resultant contraction of the diaphragm. Thus, the victim cannot breathe.

BOTULINUM TOXIN BLOCKS RELEASE OF ACH

Botulinum toxin, in contrast, exerts its lethal blow by blocking the release of ACh from the terminal button in response to a motor neuron action potential. *Clostridium botulinum* toxin causes **botulism**, a form of food poisoning. It most frequently results from improperly canned foods contaminated with clostridial bacteria, which survive and multiply, producing their toxin in the process. When this toxin is consumed, it prevents muscles from responding to nerve impulses. Death is due to respiratory failure caused by inability to contract the diaphragm. Botulinum toxin is one of the most lethal poisons known; ingesting less than 0.0001 mg can kill an adult human. (See Concepts, Challenges, and Controversies, p. 200), to learn about a surprising new wrinkle in the botulinum toxin story.)

CURARE BLOCKS ACTION OF ACH AT RECEPTOR SITES

Other chemicals interfere with neuromuscular junction activity by blocking the effect of released ACh. The best-known example is the antagonist **curare**, which reversibly binds to the ACh receptor sites on the motor end plate. Unlike ACh, however, curare does not alter membrane permeability, nor is it inactivated by AChE. When curare occupies ACh receptor sites, ACh cannot combine with these sites to open the channels that would permit the ionic movement responsible for an EPP.

Botulinum Toxin's Reputation Gets a Facelift

4

THE POWERFUL TOXIN PRODUCED by *Clostridium botulinum* causes the deadly food poisoning botulism. Yet this dreaded, highly lethal poison has been put to use as a treatment for alleviating specific movement disorders and, more recently, has been added to the list of tools that cosmetic surgeons use to fight wrinkles.

During the last decade, botulinum toxin, marketed in therapeutic doses as *Botox*, has offered welcome relief to people with a number of painful, disruptive neuromuscular diseases known categorically as **dystonias**. These conditions are characterized by spasms (excessive, sustained, involuntarily produced muscle contractions) that result in involuntary twisting or abnormal postures, depending on the body part affected. For example, painful neck spasms that twist the head to one side result from *spasmodic torticollis* (*tortus* means “twisted”; *collum* means “neck”), the most common dystonia. The problem is believed

to arise from too little inhibitory compared with excitatory input to the motor neurons that supply the affected muscle. The reasons for this imbalance in motor-neuron input are unknown. The end result of excessive motor-neuron activation is sustained, disabling contraction of the muscle supplied by the overactive motor neurons. Fortunately, injecting minuscule amounts of botulinum toxin into the affected muscle causes a reversible, partial paralysis of the muscle. Botulinum toxin interferes with the release of muscle-contraction-causing acetylcholine from the overactive motor neurons at the neuromuscular junctions in the treated muscle. The goal is to inject just enough botulinum toxin to alleviate the troublesome spasmodic contractions but not enough to eliminate the normal contractions needed for ordinary movements. The therapeutic dose is considerably less than the amount of toxin needed to induce even mild symptoms of botulinum

Consequently, because muscle action potentials cannot occur in response to nerve impulses to these muscles, paralysis ensues. When enough curare is present to block a significant number of ACh receptor sites, the person dies from respiratory paralysis caused by inability to contract the diaphragm. In the past, some people used curare as a deadly arrowhead poison.

ORGANOPHOSPHATES PREVENT INACTIVATION OF ACh
Organophosphates are a group of chemicals that modify neuromuscular junction activity in yet another way—namely, by irreversibly inhibiting AChE. Inhibition of AChE prevents the inactivation of released ACh. Death from organophosphates is also due to respiratory failure, because the diaphragm cannot

■ **TABLE 4-12** Comparison of a Synapse and a Neuromuscular Junction

Similarities	Differences
Both consist of two excitable cells separated by a narrow cleft that prevents direct transmission of electrical activity between them.	A synapse is a junction between two neurons. A neuromuscular junction exists between a motor neuron and a skeletal muscle fibre.
Axon terminals of both store chemical messengers (neurotransmitters) that are released by the Ca^{2+} -induced exocytosis of storage vesicles when an action potential reaches the terminal.	One-to-one transmission of action potentials occurs between motor neurons and muscle fibres, whereas one action potential in a presynaptic neuron usually cannot by itself bring about an action potential in a postsynaptic neuron. An action potential in a postsynaptic neuron typically occurs only when summation of EPSPs brings the membrane to threshold.
In both, binding of the neurotransmitter with receptor sites in the membrane of the cell underlying the axon terminal opens specific channels in the membrane, permitting ionic movements that alter the membrane potential of the cell.	A neuromuscular junction is always excitatory (an EPP); a synapse may be either excitatory (an EPSP) or inhibitory (an IPSP).
The resultant change in membrane potential in both cases is a graded potential.	Inhibition of skeletal muscles cannot be accomplished at the neuromuscular junction; it can occur only in the CNS through IPSPs at the dendrites and cell body of the motor neuron.

poisoning. Botulinum toxin is eventually cleared away, so its muscle-relaxing effects wear off after three to six months, at which time the treatment must be repeated.

The first dystonia for which Botox was approved as a treatment by the U.S. Food and Drug Administration (FDA) was *blepharospasm* (*blepharo* means “eyelid”). In this condition, sustained and involuntary contractions of the muscles around the eye nearly permanently close the eyelids.

Botulinum toxin’s potential as a treatment option for cosmetic surgeons was accidentally discovered when physicians noted that injections used to counter abnormal eye muscle contractions also smoothed the appearance of wrinkles in the treated areas. It turns out that frown lines, crow’s feet, and furrowed brows are caused by facial muscles that have become overactivated, or permanently

contracted, as a result of years of performing certain repetitive facial expressions. By relaxing these muscles, botulinum toxin temporarily smooths out these age-related wrinkles. Botox has recently received FDA approval as an antiwrinkle treatment. The agent is considered an excellent alternative to facelift surgery for combating lines and creases. This treatment is among the most rapidly growing cosmetic procedures in the United States, especially in the entertainment industry and in high-fashion circles. However, as with its therapeutic use to treat dystonias, the costly injections of botulinum toxin must be repeated every three to six months to maintain the desired effect in appearance. Furthermore, Botox does not work against the fine, crinkly wrinkles associated with years of excessive sun exposure, because these wrinkles are caused by skin damage, not by contracted muscles.

repolarize and return to resting conditions, then contract again to bring in a fresh breath of air. As well, many important biochemicals are organophosphates, including DNA and RNA, and many cofactors vital to life. Organophosphates are the source of many insecticides and military nerve gases.

MYASTHENIA GRAVIS INACTIVATES ACH RECEPTOR SITES

Myasthenia gravis, a disease involving the neuromuscular junction, is characterized by extreme muscular weakness (*myasthenia* means “muscular weakness”; *gravis* means “severe”). It is an autoimmune condition (*autoimmune* means “immunity against self”) in which the body erroneously produces antibodies against its own motor end-plate ACh receptors. Thus, not all the released ACh molecules can find a functioning receptor with which to bind. As a result, AChE destroys much of the ACh before it ever has a chance to interact with a receptor and contribute to the EPP. Treatment consists of administering

a drug, such as **neostigmine**, that inhibits AChE temporarily (in contrast to the toxic organophosphates, which irreversibly block this enzyme). This drug prolongs the action of ACh at the neuromuscular junction by permitting it to build up for the short term. The resultant EPP has sufficient magnitude to initiate an action potential and subsequent contraction in the muscle fibre, as it normally would.

Check Your Understanding 4.8

1. Discuss the role of ACh and of AChE at a neuromuscular junction.
2. Compare the magnitude of an EPP and an EPSP, and explain the functional significance of this difference.

Chapter in Perspective: Focus on Homeostasis

AFFERENT DIVISION

To maintain a life-sustaining stable internal environment, the body must constantly make adjustments to compensate for myriad external and internal factors that continuously threaten to disrupt homeostasis, such as external exposure to cold or internal acid production. Many of these adjustments are directed by the nervous system, one of the body’s two major regulatory systems. The CNS, the integrating and decision-making component of the

nervous system, must continuously be informed of “what’s happening” in both the internal and the external environment so that it can command appropriate responses in the organ systems to maintain the body’s viability. In other words, the CNS must know what changes are taking place before it can respond to these changes.

The afferent division of the peripheral nervous system is the communication link by which the CNS is informed about the internal and external environment. It detects, encodes, and transmits peripheral signals to the CNS for processing. Afferent input is necessary for arousal, perception, and determination of efferent output.

Afferent information about the internal environment, such as the carbon dioxide level in the blood, never reaches consciousness, but

this input to the controlling centres of the CNS is essential for maintaining homeostasis. Afferent input that reaches the level of conscious awareness, called sensory information, includes somatosensory sensation (body sense) and special senses (vision, hearing and equilibrium, taste, and smell).

The somatosensory receptors are distributed over the entire body surface as well as throughout the joints and muscles. Afferent signals from these receptors provide information about what's happening directly to each specific body part in relation to the external environment (i.e., the "what," "where," and "how much" of stimulatory inputs to the body's surface and the momentary position of the body in space). In contrast, each special sense organ is restricted to a single site in the body. Rather than provide information about a specific body part, a special sense organ provides a specific type of information about the external environment that is useful to the body as a whole. For example, through their ability to detect, extensively analyze, and integrate patterns of illumination in the external environment, the eyes and visual processing system enable you to see your surroundings. The same integrative effect could not be achieved if photoreceptors were scattered over your entire body surface, as are touch receptors.

Sensory input (somatosensory and special senses) enables a complex multicellular organism, such as a human, to interact in meaningful ways with the external environment in procuring food, defending against danger, and engaging in other behavioural actions geared toward maintaining homeostasis. In addition to providing information essential for interactions with the external environment for basic survival, the perceptual processing of sensory input adds immeasurably to the richness of life, such as enjoyment of a good book, concert, or meal.

EFFERENT DIVISION

While the afferent division of the PNS detects and carries information to the CNS for processing and decision making, the efferent division of the PNS carries directives from the CNS to the effector organs (muscles and glands), which carry out the intended response. Much of this efferent output is directed toward maintaining homeostasis.

The ANS is the efferent branch that innervates smooth and cardiac muscle, and glands. Its role in homeostatic activities is as follows:

- regulating blood pressure
- controlling digestive tract secretions, contractions, and mixing of ingested food
- controlling sweating to help maintain body temperature

The somatic nervous system is the efferent branch that innervates skeletal muscle and contributes to homeostasis by stimulating the following:

- Skeletal muscle contractions that enable body movement and postural control, which contribute to homeostasis by moving the body toward food or away from harm
- Skeletal muscle contractions that enable breathing to maintain required levels of oxygen and carbon dioxide
- Shivering thermogenesis by skeletal muscles, which helps maintain body temperature

In addition, efferent output to skeletal muscles accomplishes many movements that enrich our lives and enable us to engage in activities that contribute to society, such as dancing, building bridges, or performing surgery.

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-38)

4

1. Conversion of the energy forms of stimuli into electrical energy by the receptors is known as_____.
2. The type of stimulus to which a particular receptor is most responsive is called its_____.
3. All afferent information is sensory information. (*True or false?*)
4. Off-centre ganglion cells increase their rate of firing when a beam of light strikes the periphery of their receptive field. (*True or false?*)
5. During dark adaptation, rhodopsin is gradually regenerated to increase the sensitivity of the eyes. (*True or false?*)
6. An optic nerve carries information from the lateral and medial halves of the same eye, whereas an optic tract carries information from the lateral half of one eye and the medial half of the other. (*True or false?*)
7. Displacement of the round window generates neural impulses perceived as sound sensations. (*True or false?*)
8. Hair cells in different regions of the organ of Corti and neurons in different regions of the auditory cortex are activated by different tones. (*True or false?*)
9. Each taste receptor responds to just one of the five primary tastes. (*True or false?*)
10. Rapid adaptation to odours results from adaptation of the olfactory receptors. (*True or false?*)

(l) sclera

- ___ 1. layer that contains photoreceptors
- ___ 2. point from which optic nerve leaves retina
- ___ 3. forms white part of eye
- ___ 4. thalamic structure that processes visual input
- ___ 5. coloured diaphragm of muscle that controls amount of light entering eye
- ___ 6. contributes most to eye's refractive ability
- ___ 7. supplies nutrients to lens and cornea
- ___ 8. produces aqueous humour

11. Match the following:

- (a) choroid
- (b) aqueous humour
- (c) fovea
- (d) lateral geniculate nucleus
- (e) cornea
- (f) retina
- (g) lens

- ___ 9. contains vascular supply for retina and a pigment that minimizes scattering of light within eye (h) optic disc; blind spot (i) iris
- ___ 10. has adjustable refractive ability
- ___ 11. portion of retina with greatest acuity (j) ciliary body
- ___ 12. point at which fibres from medial half of each retina cross to opposite side (k) optic chiasm

12. Using the answer code on the right, indicate which properties apply to taste and/or smell:

- a. applies to taste
- b. applies to smell
- c. applies to both taste and smell
- ___ 1. Receptors are separate cells that synapse with terminal endings of afferent neurons.
- ___ 2. Receptors are specialized endings of afferent neurons.
- ___ 3. Receptors are regularly replaced.
- ___ 4. Specific chemicals in the environment attach to special binding sites on the receptor surface, leading to a depolarizing receptor potential.
- ___ 5. There are two processing pathways: a limbic system route and a thalamic-cortical route.
- ___ 6. The discriminative ability is based on patterns of receptor stimulation by five different modalities.
- ___ 7. A thousand different receptor types are used.
- ___ 8. Information from receptor cells is filed and sorted by neural junctions called glomeruli.

13. Sympathetic preganglionic fibres begin in the thoracic and lumbar segments of the spinal cord. (*True or false?*)

14. Action potentials are transmitted on a one-to-one basis at both a neuromuscular junction and a synapse. (*True or false?*)

15. Which statement correctly describes the sympathetic nervous system?

- a. It is always excitatory.
- b. It innervates only tissues concerned with protecting the body against challenges from the outside environment.
- c. It has short preganglionic and long postganglionic fibres.
- d. It is part of the afferent division of the peripheral nervous system.
- e. It is part of the somatic nervous system.

16. Which statement correctly describes acetylcholinesterase?
 - a. It is stored in vesicles in the terminal button.
 - b. It combines with receptor sites on the motor end plate to bring about an end-plate potential.
 - c. It is inhibited by organophosphates.
 - d. It is the chemical transmitter at the neuromuscular junction.
 - e. It paralyzes skeletal muscle by strongly binding with acetylcholine receptor sites.
17. The two divisions of the ANS are the _____ nervous system, which dominates in fight-or-flight situations, and the _____ nervous system, which dominates in rest-and-digest situations.
18. The _____ is a modified sympathetic ganglion that does not give rise to postganglionic fibres, but instead secretes hormones similar or identical to sympathetic postganglionic neurotransmitters into the blood.
19. Using the answer code on the right, identify the autonomic transmitter being described:

___ 1. secreted by all preganglionic fibres	(a) acetylcholine
___ 2. secreted by sympathetic postganglionic fibres	(b) norepinephrine
___ 3. secreted by parasympathetic postganglionic fibres	
___ 4. secreted by the adrenal medulla	
___ 5. secreted by motor neurons	
___ 6. binds to muscarinic or nicotinic receptors	
___ 7. binds to α or β receptors	
20. Using the answer code on the right, indicate which type of efferent output is being described:

___ 1. composed of two-neuron chains	(a) characteristic of the somatic nervous system
___ 2. innervates cardiac muscle, smooth muscle, and glands	(b) characteristic of the autonomic nervous system
___ 3. innervates skeletal muscle	
___ 4. consists of the axons of motor neurons	
___ 5. exerts either an excitatory or an inhibitory effect on its effector organs	
___ 6. dually innervates its effector organs	
___ 7. exerts only an excitatory effect on its effector organs	
8. What are sound waves? What is responsible for the pitch, intensity, and timbre of a sound?
9. Describe the function of each of the following parts of the ear: pinna, ear canal, tympanic membrane, ossicles, oval window, and the various parts of the cochlea. Include a discussion of how sound waves are transduced into action potentials.
10. Discuss the functions of the semicircular canals, the utricle, and the saccule.
11. Describe the location, structure, and activation of the receptors for taste and smell.
12. Compare the processes of colour vision, hearing, taste, and smell discrimination.
13. Distinguish between preganglionic and postganglionic fibres.
14. Compare the origin, preganglionic and postganglionic fibre length, and neurotransmitters of the sympathetic and parasympathetic nervous systems.
15. What is the advantage of dual innervation of many organs by both branches of the ANS?
16. Distinguish among the following types of receptors: nicotinic receptors, muscarinic receptors, α_1 receptors, α_2 receptors, β_1 receptors, and β_2 receptors.
17. What regions of the CNS regulate autonomic output?
18. Why are motor neurons called the “final common pathway”?
19. Describe the sequence of events that occurs at a neuromuscular junction.
20. Discuss the effect each of the following has at the neuromuscular junction: black widow spider venom, botulinum toxin, curare, myasthenia gravis, and organophosphates.

Quantitative Exercises (Solutions in Appendix E, p. A-39)

1. Calculate the difference in the time it takes for an action potential to travel 1.3 m between the slow (12 m/sec) and fast (30 m/sec) pain pathways.
2. Have you ever noticed that humans have circular pupils, whereas cats' pupils are more elongated from top to bottom? For simplicity in calculation, assume the cat pupil is rectangular. The following calculations will help you understand the implication of this difference. For simplicity, assume a constant intensity of light.
 - a. If the diameter of a human's circular pupil were decreased by half on contraction of the constrictor muscle of the iris, by what percentage would the amount of light allowed into the eye be decreased?
 - b. If a cat's rectangular pupil were decreased by half along one axis only, by what percentage would the amount of light allowed into the eye be decreased?
 - c. Comparing these calculations, do humans or cats have more precise control over the amount of light falling on the retina?

Written Questions

1. List and describe the receptor types according to their adequate stimulus.
2. Compare tonic and phasic receptors.
3. Explain how acuity is influenced by receptive field size and by lateral inhibition.
4. Compare the fast and slow pain pathways.
5. Describe the built-in analgesic system of the brain.
6. Describe the process of phototransduction.
7. Compare the functional characteristics of rods and cones.

3. A decibel is the unit of sound level, β , defined as follows:

$$\beta = (10 \text{ dB}) \log_{10} \left(\frac{l}{l_0} \right),$$

where l is *sound intensity*, or the rate at which sound waves transmit energy per unit area. The units of l are watts per square metre (W/m^2). l_0 is a constant intensity close to the human hearing threshold, namely, 10^{-12} W/m^2 .

- a. For the following sound levels, calculate the corresponding sound intensities:
- (1) 20 dB (a whisper)
 - (2) 70 dB (a car horn)
 - (3) 120 dB (a low-flying jet)
 - (4) 170 dB (a space shuttle launch)
- b. Explain why the sound levels of these sounds increase by the same increment (i.e., each sound is 50 dB higher than the one preceding it), yet the incremental increases in sound intensities you calculated are so different. What implications does this have for performance of the human ear?

4. When a muscle fibre is activated at the neuromuscular junction, tension does not begin to rise until about 1 millisecond after initiation of the action potential in the muscle fibre. Many things occur during this delay, one time-consuming event being diffusion of acetylcholine across the neuromuscular junction. The following equation can be used to calculate how long this diffusion takes:

$$t = \frac{x^2}{2D}$$

In this equation, x is the distance covered, D is the diffusion coefficient, and t is the time it takes for diffusion of the substance across the distance x . In this example, x is the width of the cleft between the neuronal axon terminal and the muscle fibre at the neuromuscular junction (assume 200 nm), and D is the diffusion coefficient of acetylcholine (assume $1 \times 10^{-5} \text{ cm}^2/\text{sec}$). How long does it take the acetylcholine to diffuse across the neuromuscular junction?

POINTS TO PONDER

(Explanations in Appendix E, p. A-39)

1. Patients with certain nerve disorders are unable to feel pain. Why is this disadvantageous?
2. Ophthalmologists frequently instill eye drops in their patients' eyes to bring about pupillary dilation, which makes it easier for the physician to view the eye's interior. In what way would the drug in the eye drops affect ANS activity in the eye to cause the pupils to dilate?
3. A patient complains of not being able to see the right half of the visual field with either eye. At what point in the patient's visual pathway does the defect lie?
4. Explain how middle ear infections interfere with hearing. Of what value are the tubes that are sometimes surgically placed in the eardrums of patients with a history of repeated middle ear infections accompanied by chronic fluid accumulation?
5. Explain why your sense of smell is reduced when you have a cold, even though the cold virus does not directly adversely affect the olfactory receptor cells.
6. Explain why epinephrine, which causes arteriolar constriction (narrowing) in most tissues, is frequently administered in conjunction with local anesthetics.
7. Would skeletal muscle activity be affected by atropine? Why or why not?
8. Considering that you can voluntarily control the emptying of your urinary bladder by contracting (preventing emptying) or relaxing (permitting emptying) your external urethral sphincter, a ring of muscle that guards the exit from the bladder, of what type of muscle is this sphincter composed and what branch of the nervous system supplies it?
9. The venom of certain poisonous snakes contains a bungarotoxin, which binds tenaciously to acetylcholine receptor sites on the motor end-plate membrane. What would the resultant symptoms be?
10. Explain how destruction of motor neurons by poliovirus or amyotrophic lateral sclerosis can be fatal.

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-40)

Suzanne J. complained to her physician of bouts of dizziness. The physician asked her whether by "dizziness" she meant a feeling of lightheadedness, as if she were going to faint (a condition known as *syncope*), or a feeling that she or surrounding objects in the

room were spinning around (a condition known as *vertigo*). Why is this distinction important in the differential diagnosis of her condition? What are some possible causes of each of these symptoms?

The Endocrine System

Body systems maintain homeostasis

Anatomical Travelogue/Science Source

Endocrine system

Cells make up body systems

Homeostasis

The endocrine system, one of the body's two major regulatory systems, secretes hormones that act on their target cells to regulate the blood concentrations of nutrient molecules, water, salt, and other electrolytes, among other homeostatic activities. Hormones also play a key role in controlling growth and reproduction and in stress adaptation.

Homeostasis is essential for survival of cells

© OZ creationz/Shutterstock

Endocrine parathyroid

The endocrine system regulates activities that require duration rather than speed. Endocrine glands release hormones: the blood-borne chemical messengers that act on target cells located a long distance from the endocrine gland. Most target-cell activities under hormonal control are directed toward maintaining homeostasis. The central endocrine glands, which are in or closely associated with the brain, include the hypothalamus, the pituitary gland, and the pineal gland. The hypothalamus (a part of the brain) and posterior pituitary gland act as a unit

to release hormones essential for maintaining water balance, giving birth, and breastfeeding. The hypothalamus also secretes regulatory hormones that control the hormonal output of the anterior pituitary gland, which secretes six hormones that, in turn, largely control the hormonal output of several peripheral endocrine glands. One anterior pituitary hormone, growth hormone, promotes growth and influences nutrient homeostasis. The pineal gland is a part of the brain that secretes a hormone important in establishing the body's biological rhythms.

Clinical Connections

Michael is a 13-year-old male of African Canadian descent. As a younger child Michael always seemed happy and healthy and engaged in school and social life typical for his age. However, as he started getting older, his childish face and chubby body stayed looking young. In contrast, his friends were growing taller and showing signs of puberty. Michael started to withdraw from his friends, stopped playing sports, and when not at school, spent all his time at home. Concerned for his well-being, his mother took him to their family physician.

At the physician's office, Michael said that he is teased for being the shortest boy in his gym class. When his height was measured and compared to the growth charts, his height showed up as the lowest for his age. An X-ray of his hand revealed the bone age of a 10-year-old boy. Blood tests taken to measure the various hormones involved in growth showed he had normal levels of the growth hormone-releasing hormone, very low levels of growth hormone, and low levels of insulin-like growth factor. Michael was diagnosed with pituitary dwarfism.

5.1 General Principles of Endocrinology

The **endocrine system** consists of the ductless endocrine glands (p. 7) scattered throughout the body (► Figure 5-1). Even though the endocrine glands for the most part are not connected anatomically, they constitute a system in a functional sense. They all accomplish their functions by secreting hormones into the blood, and many functional

FIGURE 5-1 The endocrine system

interactions take place among the various endocrine glands. Once secreted, a hormone travels in the blood to its distant target cells, where it regulates or directs a particular function. **Endocrinology** is the study of the homeostatic chemical adjustments and other activities that hormones accomplish.

A hormone is a chemical substance that is secreted in low quantities into the blood by a cell or grouping of cells and exerts a physiological effect on specific target tissue (or cells). Although the blood distributes hormones throughout the body, only specific target cells can respond to each hormone, because only the target cells have receptors for binding with the particular hormone (p. 32). The binding of a hormone with its specific target-cell receptors initiates a chain of events within the target cells to bring about the hormone's final effect. Pages 217–221 explain in detail how most hormones initiate their effect by first combining with a receptor that is located either on the cell membrane or inside the cell. A cell may have several different receptors that recognize the same hormone and activate different signalling pathways, or, in contrast, different hormones and their receptors may summon the same biochemical pathway.

Hormones

The endocrine system is one of the body's two major regulatory systems; the other is the nervous system (Chapters 3 and 4). Recall that the nervous system is specialized for controlling different types of activities. In general, the nervous system coordinates rapid, precise responses and is especially important in mediating the body's interactions with the external environment. The endocrine system, by contrast, primarily controls activities that require duration rather than speed. It regulates, coordinates, and integrates cellular and organ function at a distance.

OVERALL FUNCTIONS OF THE ENDOCRINE SYSTEM

1. Regulating organic metabolism and water and electrolyte balance, which are important collectively in maintaining a constant internal environment
2. Inducing adaptive changes to help the body cope with stressful situations
3. Promoting smooth, sequential growth and development

4. Controlling reproduction
5. Regulating red blood cell production
6. Along with the autonomic nervous system, controlling and integrating both circulation and the digestion and absorption of food

TROPIC HORMONES

Some hormones regulate the production and secretion of another hormone. A hormone that has as its primary function the regulation of hormone secretion by another endocrine gland is classified functionally as a **tropic hormone** (*tropic* means “nourishing”). Tropic hormones stimulate and maintain their endocrine target tissues. For example, the tropic hormone thyroid-stimulating hormone (TSH), from the anterior pituitary, stimulates thyroid hormone secretion by the thyroid gland and also maintains the structural integrity of this gland. In the absence of TSH, the thyroid gland atrophies (shrinks) and produces very low levels of its hormone.

COMPLEXITY OF ENDOCRINE FUNCTION

The following factors add to the complexity of the system:

- A single endocrine gland may produce multiple hormones. For example, the thyroid gland produces thyroxine, triiodothyronine, and calcitonin.
- A single hormone may be secreted by more than one endocrine gland. For example, the hypothalamus, pancreas, and stomach all secrete the hormone somatostatin, and the stomach also releases somatostatin that acts as a paracrine (a chemical released to adjoining cells or surrounding tissues).
- Frequently, a single hormone has more than one type of target cell and therefore can induce more than one type of effect. An example of this is oxytocin, which contracts the uterus during birth and also acts on the myoepithelial cells in the breasts to assist in expelling milk when the baby suckles.
- The rate of secretion of some hormones varies considerably over time in a cyclic pattern. Therefore, endocrine systems also provide temporal (time) coordination of function. This is particularly apparent in endocrine control of reproductive cycles, such as the menstrual cycle, in which normal functioning requires highly specific patterns of change in the secretion of various hormones.
- A single target cell may be influenced by more than one hormone. Some cells contain an array of receptors for responding in different ways to different hormones. To illustrate, insulin promotes the conversion of glucose into glycogen within liver cells by stimulating one particular hepatic enzyme; whereas another hormone, glucagon, by activating yet another hepatic enzyme, enhances the degradation of glycogen into glucose within liver cells.
- The same chemical messenger may be either a hormone or a neurotransmitter, depending on its source and mode of delivery to the target cell. Norepinephrine, which is secreted as a hormone by the adrenal medulla and released as a neurotransmitter from sympathetic postganglionic nerve fibres, is a prime example.
- Some organs are exclusively endocrine in function (they specialize in hormone secretion alone, the anterior pituitary

being an example), whereas other organs of the endocrine system perform nonendocrine functions in addition to secreting hormones. For example, the testes produce sperm and also secrete the male sex hormone testosterone.

Plasma concentration

The primary function of most hormones is the regulation of various homeostatic activities. Because hormones' effects are proportional to their concentrations in the plasma, these concentrations are subject to control according to homeostatic need. The effective plasma concentration of a free, biologically active hormone—and thus the hormone's availability to its receptors—depends on several factors: (1) the hormone's rate of secretion into the blood by the endocrine gland; (2) for a few hormones, its rate of metabolic activation; (3) for lipophilic hormones, its extent of binding to plasma proteins; and (4) its rate of removal from the blood by metabolic inactivation and excretion in the urine. Furthermore, the magnitude of the hormonal response depends on the availability and sensitivity of the target cells' receptors for the hormone. However, the quantity of hormones (concentration) in the blood is small: ranging from 1 picogram (1 millionth of a millionth of a gram) per millilitre of blood to a few micrograms (1 millionth of a gram) per millilitre of blood. The rate of secretion, also small, is typically measured in micrograms or milligrams per day.

We first examine the factors that influence the plasma concentration of the hormone and then turn our attention to the target cells' responsiveness to the hormone.

Normally, the effective plasma concentration of a hormone is regulated by appropriate adjustments in the rate of its secretion. Endocrine glands do not secrete their hormones at a constant rate; the secretion rates of all hormones vary, subject to control often by a combination of several complex mechanisms. The regulatory system for each hormone is considered in detail in later sections. For now, we will address the general mechanisms of controlling secretion that are common to many different hormones: negative-feedback control, neuroendocrine reflexes, and diurnal (circadian) rhythms.

NEGATIVE-FEEDBACK CONTROL

Negative feedback is a prominent feature of hormonal control systems. Stated simply, *negative feedback exists when the output of a system counteracts a change in input*, thereby maintaining a controlled variable within a narrow range around a set level (p. 14). Negative feedback maintains the plasma concentration of a hormone at a given level, similar to the way a home heating system maintains the room temperature at a given set point. Control of hormonal secretion provides some classic physiological examples of negative feedback. For example, when the plasma concentration of free circulating thyroid hormone falls below a given set point, the anterior pituitary secretes thyroid-stimulating hormone (TSH), which stimulates the thyroid to increase its secretion of thyroid hormone (Figure 5-2). Thyroid hormone, in turn, inhibits further secretion of TSH by the anterior pituitary. Negative feedback ensures that once thyroid gland secretion has been “turned on” by TSH, it will not continue unabated, but will be “turned off” when the appropriate level of free circulating thyroid hormone has been achieved. Thus, the effect of a particular hormone's actions can inhibit its own secretion. The feedback loops

► FIGURE 5-2 Negative-feedback control

often become quite complex to the extent that several endocrine tissues and hormones, or other messengers, may be involved.

Although the majority of endocrine feedback systems are negative, it is important to mention that some feedback loops are **positive-feedback** loops. Simplistically, positive feedback means that the actions of a hormone cause the further release of the hormone. Such mechanisms tend to be self-perpetuating and out of control, which is contrary to the concept of homeostasis; this is why such systems are not common. An excellent example of a positive-feedback loop is the role of oxytocin in child birth (parturition) (see Figure 17-30).

NEUROENDOCRINE REFLEXES

Many endocrine control systems involve **neuroendocrine reflexes**, which include neural as well as hormonal components. The purpose of such reflexes is to produce a sudden increase in hormone secretion (i.e., “turn up the thermostat setting”) in response to a specific stimulus, frequently a stimulus external to the body. In some instances, neural input to the endocrine gland is the only factor regulating secretion of the hormone. For example, secretion of epinephrine by the adrenal medulla is solely controlled by the sympathetic nervous system. Some endocrine control systems, in contrast, include both feedback control (which maintains a constant basal level of the hormone) and neuroendocrine reflexes (which cause sudden bursts in secretion in response to a sudden increased need for the hormone). An example is the increased secretion of cortisol, the “stress hormone,” by the adrenal cortex during a stress response (see Figure 6-8).

DIURNAL (CIRCADIAN) RHYTHMS

The secretion rates of many hormones rhythmically fluctuate up and down as a function of time. The most common endocrine rhythm is the **diurnal (circadian) rhythm** (*diurnal* means “day–night”; *circadian* means “around a day”), which is characterized by repetitive oscillations in hormone levels that are very regular and cycle once every 24 hours. This rhythmicity is caused by endogenous oscillators similar to the self-paced respiratory neurons in the brain stem that control the rhythmic motions of breathing, except that the time-keeping oscillators cycle on a much longer time scale. Furthermore, unlike the rhythmicity of breathing, endocrine rhythms are locked

► FIGURE 5-3 Diurnal rhythm of cortisol secretion

on, or **entrained**, to external cues, such as the light–dark cycle. That is, the inherent 24-hour cycles of peak and ebb of hormone secretion are set to “march in step” with cycles of light (period of activity) and dark (period of inactivity). For example, cortisol secretion rises during the night, reaches its peak secretion in the morning before a person gets up, then falls throughout the day to its lowest level at bedtime (► Figure 5-3). Inherent hormonal rhythmicity and entrainment are not accomplished by the endocrine glands themselves but result from the central nervous system changing the set point of these glands. We discuss the master biological clock further in Section 5.7. Negative-feedback control mechanisms operate to maintain whatever set point is established for that time of day. Some endocrine cycles operate on time scales other than a circadian rhythm; a well-known example is the monthly menstrual cycle.

Transport, metabolism, and excretion

Even though the effective plasma concentration of a hormone is normally regulated by adjusting its rate of secretion, alterations in its transport, metabolism, or excretion can also influence the hormone’s plasma concentration, sometimes inappropriately (Appendix F lists reference values). For example, because the liver synthesizes plasma proteins, liver disease may result in abnormal endocrine activity by altering the balance between free and bound pools of lipophilic hormones.

Eventually, all hormones are metabolized by enzyme-mediated reactions that modify the hormonal structure in some way. In most cases, this process *inactivates* the hormone. However, in some cases, metabolism *activates* a hormone; that is, the hormone’s product has greater activity than the original hormone. For example, after the thyroid hormone thyroxine is secreted, it is converted to a more powerful hormone by enzymatic removal of one of its iodine atoms. Usually the rate of such hormone activation is itself under hormonal control. The liver is the most common site for metabolic hormone inactivation, but some hormones are also inactivated in the blood, kidneys, or target cells.

Hormones and their metabolites are typically eliminated from the blood by urinary excretion. In contrast to the tight controls on hormone secretion, hormone inactivation and excretion are not regulated.

The amount of time after a hormone is secreted before it is inactivated, and the means by which this takes place, differ for different

classes of hormones. In general, the hydrophilic peptides and catecholamines are easy targets for blood and tissue enzymes, so they remain in the blood only briefly (a few minutes to a few hours) before being enzymatically inactivated. In the case of some peptide hormones, such as insulin, the target cell actually engulfs the bound hormone by endocytosis and degrades it intracellularly. In contrast, binding of lipophilic hormones to plasma proteins makes them less vulnerable to metabolic inactivation and keeps them from escaping into urine. Therefore, lipophilic hormones are removed from plasma much more slowly. They may persist in the blood for hours (steroids) or up to a week (thyroid hormone). Lipophilic hormones typically undergo a series of reactions that reduce their biological activity and make them more water soluble so they can be freed from their plasma protein carriers and be eliminated in the urine.

 When liver and kidney function are normal, the measuring of urinary concentrations of hormones and their metabolites provides a useful, noninvasive way to assess endocrine function, because the rate of excretion of these products in the urine directly reflects their rate of secretion by the endocrine glands. Because the liver and kidneys are important in removing hormones from the blood, patients with liver or kidney disease may suffer from excess activity of certain hormones solely because hormone elimination is reduced.

Endocrine disorders

 Abnormalities in a hormone’s effective plasma concentration can arise from a variety of factors (■ Table 5-1). Endocrine disorders most commonly result from abnormal plasma concentrations of a hormone caused by inappropriate rates of secretion—that is, too little hormone secreted (**hyposecretion**) or too much hormone secreted (**hypersecretion**). Occasionally, endocrine dysfunction arises because target-cell responsiveness to the hormone is abnormally low, even though plasma concentration of the hormone is normal.

■ TABLE 5-1 Means by Which Endocrine Disorders Can Arise

Too Little Hormone Activity	Too Much Hormone Activity
Too little hormone secreted by the endocrine gland (hyposecretion)*	Too much hormone secreted by the endocrine gland (hypersecretion)*
Increased removal of the hormone from the blood	Reduced plasma protein binding of the hormone (too much free, biologically active hormone)
Abnormal tissue responsiveness to the hormone	Decreased removal of the hormone from the blood
Lack of target-cell receptors	Decreased inactivation
Lack of an enzyme essential to the target-cell response	Decreased excretion

* Most common causes of endocrine dysfunction

HYPOSECRETION

Primary hyposecretion occurs when an endocrine gland is secreting too little of its hormone because of an abnormality within that gland. *Secondary hyposecretion* takes place when an endocrine gland is functioning normally but is secreting too little hormone because of a deficiency of its tropic hormone.

The following are among the many different factors (each listed with an example) that may cause primary hyposecretion: (1) genetic (inborn absence of an enzyme that catalyzes synthesis of the hormone); (2) dietary (lack of iodine, which is needed for synthesis of thyroid hormone); (3) chemical or toxic (certain insecticide residues may destroy the adrenal cortex); (4) immunological (autoimmune antibodies may destroy the body’s own thyroid tissue); (5) other disease processes (cancer or tuberculosis may coincidentally destroy endocrine glands); (6) *iatrogenic* (physician induced, such as surgical removal of a cancerous thyroid gland); and (7) *idiopathic* (meaning the cause is not known).

The most common method of treating hormone hyposecretion is to administer a hormone that is the same as (or similar to, such as from another species) the deficient or missing one. Such replacement therapy seems straightforward, but the hormone’s source and means of administration involve some practical problems. The sources of hormone preparation for clinical use include (1) endocrine tissues from domestic livestock, (2) placental tissue and urine of pregnant women, (3) laboratory synthesis of hormones, and (4) “hormone factories,” or bacteria into which genes coding for the production of human hormones have been introduced. The method of choice for a given hormone is determined largely by its structural complexity and degree of species specificity.

HYPERSECRETION

Like *hyposecretion*, *hypersecretion* by a particular endocrine gland is designated as primary or secondary depending on whether the defect lies in that gland or is due to excessive stimulation from the outside, respectively. Hypersecretion may be caused by (1) tumours that ignore the normal regulatory input and continuously secrete excess hormone and (2) immunological factors, such as excessive stimulation of the thyroid gland by an abnormal antibody that mimics the action of TSH, the thyroid tropic hormone. Excessive levels of a particular hormone may also arise from substance abuse, such as the outlawed practice among athletes of using certain steroids that increase muscle mass by promoting protein synthesis in muscle cells.

There are several ways of treating hormonal hypersecretion. If a tumour is the culprit, it may be surgically removed or destroyed with radiation treatment. In some instances, hypersecretion can be limited by drugs that block hormone synthesis or inhibit hormone secretion. Sometimes the condition may be treated by giving drugs that inhibit the action of the hormone without actually reducing the excess hormone secretion.

ABNORMAL TARGET-CELL RESPONSIVENESS

Endocrine dysfunction can also occur because target cells do not respond adequately to the hormone, even though the effective plasma concentration of a hormone is normal. This unresponsiveness may be caused, for example, by an inborn

lack of receptors for the hormone, as in *testicular feminization syndrome*. In this condition, receptors for testosterone, a masculinizing hormone produced by the male testes, are not produced because of a specific genetic defect. Although adequate testosterone is available, masculinization does not take place, just as if no testosterone were present. Abnormal responsiveness may also occur if the target cells for a particular hormone lack an enzyme essential to carrying out the response.

Target cells

In contrast to endocrine dysfunction caused by *unintentional* receptor abnormalities, the target-cell receptors for a particular hormone can be *deliberately altered* as a result of physiological control mechanisms. A target cell's response to a hormone is correlated with the number of the cell's receptors occupied by molecules of that hormone, which in turn depends not only on the plasma concentration of the hormone but also on the number of receptors in the target cell for that hormone. Thus, the response of a target cell to a given plasma concentration of hormone can be fine-tuned up or down by varying the number of receptors available for hormone binding. The number of receptors in a target cell does not remain constant from minute to minute because receptors are destroyed and new ones are manufactured by the cell.

DOWN REGULATION

As an illustration of this fine-tuning, when the plasma concentration of insulin is chronically elevated, the total number of target-cell receptors for insulin is reduced as a direct result of the effect an elevated level of insulin has on the insulin receptors. This phenomenon, known as **down regulation**, constitutes an important locally acting negative-feedback mechanism that prevents the target cells from overreacting to the high concentration of insulin; that is, the target cells are *desensitized* to insulin, helping blunt the effect of insulin hypersecretion.

Down regulation of the insulin receptor is accomplished by the following mechanism. The binding of insulin to its surface receptors induces endocytosis of the hormone-receptor complex, which is subsequently attacked by intracellular lysosomal enzymes. This internalization serves a twofold purpose: it provides a pathway for degrading the hormone and helps regulate the number of receptors available for binding on the target cell's surface. At high plasma insulin concentrations, the number of surface receptors for insulin is gradually reduced by the accelerated rate of receptor internalization and degradation, brought about by increased hormonal binding. The rate of synthesis of new receptors within the endoplasmic reticulum and their insertion in the plasma membrane do not keep pace with their rate of destruction. Over time, this self-induced loss of target-cell receptors for insulin reduces the target cell's sensitivity to the elevated hormone concentration.

PERMISSIVENESS, SYNERGISM, AND ANTAGONISM

A given hormone's effects are influenced not only by the concentration of the hormone itself but also by the concentrations of other hormones that interact with it. Because hormones are widely distributed through the blood, target cells may be

simultaneously exposed to many different hormones, giving rise to numerous complex hormonal interactions on target cells. Hormones frequently alter the receptors for other kinds of hormones as part of their normal physiological activity. A hormone can influence the activity of another hormone at a given target cell in one of three ways: permissiveness, synergism, and antagonism.

- With **permissiveness**, one hormone must be present in adequate amounts for the full exertion of another hormone's effect. In essence, the first hormone, by enhancing a target cell's responsiveness to another hormone, "permits" this other hormone to exert its full effect. For example, thyroid hormone increases the number of receptors for epinephrine in epinephrine's target cells, increasing the effectiveness of epinephrine. In the absence of thyroid hormone, epinephrine is only marginally effective.
- **Synergism** occurs when the actions of several hormones are complementary and their combined effect is greater than the sum of their separate effects. An example is the synergistic action of follicle-stimulating hormone and testosterone, both of which are required for maintaining the normal rate of sperm production. Synergism results from each hormone's influence on the number or affinity of receptors for the other hormone.
- **Antagonism** occurs when hormones have opposing effects. For example, in regulating plasma calcium (Ca^{2+}) concentrations, the hormone calcitonin promotes the incorporation of Ca^{2+} into bone, whereas the hormone parathyroid hormone stimulates the release of Ca^{2+} from bone. Another example of antagonism is the actions of insulin and glucagon on regulating both cellular metabolism and plasma glucose concentrations.

5.2 Principles of Hormonal Communication

Hydrophilic or lipophilic

Hormones are not all similar chemically but instead fall into two distinct groups based on their solubility properties: hydrophilic or lipophilic hormones. Hormones within each group are further classified according to their biochemical structure and/or source as follows (Table 5-2):

1. **Hydrophilic hormones** (water-loving) are highly water soluble and have low lipid solubility. Most hydrophilic hormones are peptide or protein hormones consisting of specific amino acids arranged in a chain of varying length. The shorter chains are peptides, and the longer ones are proteins. For convenience, we will refer to this entire category as *peptides*. An example is insulin from the pancreas. Another group of hydrophilic hormones are the *catecholamines*, which are derived from the amino acid tyrosine and are specifically secreted by the adrenal medulla. The adrenal gland consists of an inner adrenal medulla surrounded by an outer adrenal cortex. (You will learn more about the location and structure of

TABLE 5-2 Chemical Classification of Hormones

Properties	Peptides	AMINES		
		Catecholamines	Thyroid Hormone	Steroids
Solubility	Hydrophilic	Hydrophilic	Lipophilic	Lipophilic
Structure	Chains of specific amino acids	Tyrosine derivative	Iodinated tyrosine derivative	Cholesterol derivative
Synthesis	In rough endoplasmic reticulum; packaged in Golgi complex	In cytosol	In colloid, an inland extracellular site	Stepwise modification of cholesterol molecule in various intracellular compartments
Storage	Large amounts in secretory granules	In chromaffin granules	In colloid	Not stored; cholesterol precursor stored in lipid droplets
Secretion	Exocytosis of granules	Exocytosis of granules	Endocytosis of colloid	Simple diffusion
Transport in Blood	As free hormone	Half bound to plasma proteins	Mostly bound to plasma proteins	Mostly bound to plasma proteins
Receptor Site	Surface of target cell	Surface of target cell	Inside target cell	Inside target cell
Mechanism of Action	Channel changes or activation of second-messenger system to alter activity of target proteins that produce the effect	Activation of second-messenger system to alter activity of target proteins that produce the effect	Activation of specific genes to make new proteins that produce the effect	Activation of specific genes to make new proteins that produce the effect
Hormones of this Type	Majority of hormones	Only hormones from the adrenal medulla	Only hormones from the thyroid follicular cells	Hormones from the adrenal cortex and gonads

5

the endocrine glands in Chapter 6.) Epinephrine is the primary catecholamine secreted by the adrenal medulla.

2. **Lipophilic hormones** (lipid-loving) have high lipid solubility and are poorly soluble in water. Lipophilic hormones include *thyroid hormone* and the *steroid hormones*. Thyroid hormone, as its name implies, is secreted exclusively by the thyroid gland. Thyroid hormone is an iodinated tyrosine derivative. Even though catecholamines and thyroid hormone behave very differently, they are sometimes grouped together as *amine hormones* because of their common tyrosine derivation. Steroids are neutral lipids derived from cholesterol. The hormones secreted by the adrenal cortex, such as cortisol, and the sex hormones (testosterone in males and estrogen in females) secreted by the reproductive organs are all steroids.

Minor differences in chemical structure between hormones within each category often result in profound differences in biological response. Comparing two steroid hormones in > Figure 5-4, for example, note the subtle difference between

testosterone, the male sex hormone responsible for inducing the development of masculine characteristics, and estradiol, a form of estrogen, which is the feminizing female sex hormone.

The solubility properties of a hormone determine the means by which (1) the hormone is processed by the endocrine cell,

> FIGURE 5-4 Comparison of two steroid hormones, testosterone and estradiol.

From Sherwood: Human Physiology, 8E. © 2013 Brooks/Cole, a part of Cengage, Inc. Reproduced by permission. www.cengage.com/permissions

(2) the way the hormone is transported in the blood, and (3) the mechanism by which the hormone exerts its effects at the target cell. First we consider the different ways these hormone types are processed at their site of origin—the endocrine cell—and then we compare their means of transport and their mechanisms of action.

The mechanisms of synthesis, storage, and secretion

Because of their chemical differences, the means by which the various types of hormones are synthesized, stored, and secreted differ.

PROCESSING OF HYDROPHILIC PEPTIDE HORMONES

Peptide hormones are synthesized and secreted by the same steps used for manufacturing any protein that is exported from the cell. From the time peptide hormones are synthesized until they are secreted, they are always segregated from intracellular proteins through containment in membrane-enclosed compartments. Here is a brief overview of the steps:

1. Prehormones, or precursor proteins, are synthesized by ribosomes on the rough endoplasmic reticulum (ER). They then migrate to the Golgi complex in membrane-enclosed vesicles that pinch off from the smooth ER.
2. During their journey through the ER and Golgi complex, the large prehormone precursor molecules are processed to become active hormones.
3. The Golgi complex then packages the finished hormones into secretory vesicles that are pinched off and stored in the cytoplasm until an appropriate signal triggers their secretion.
4. On appropriate stimulation, the secretory vesicles fuse with the plasma membrane and release their contents to the outside by exocytosis (p. 49). Such secretion usually does not go on continuously; it is triggered only by specific stimuli. The blood then picks up the secreted hormone for distribution.

PROCESSING OF LIPOPHILIC STEROID HORMONES

All steroidogenic (steroid-producing) cells perform the following steps to produce and release their hormonal product:

1. Cholesterol is the common precursor for all steroid hormones.
2. Synthesis of the various steroid hormones from cholesterol requires a series of enzymatic reactions that modify the basic cholesterol molecule—for example, by varying the type and position of side groups attached to the cholesterol framework. Each conversion from cholesterol to a specific steroid hormone requires the help of a number of enzymes that are limited to certain steroidogenic organs. Accordingly, each steroidogenic organ can produce only the steroid hormone or hormones for which it has a complete set of appropriate enzymes. For example, a key enzyme necessary for producing cortisol is found only in the adrenal

cortex, so no other steroidogenic organ can produce this hormone.

3. Unlike peptide hormones, steroid hormones are not stored. Once formed, the lipid-soluble steroid hormones immediately diffuse through the steroidogenic cell's lipid plasma membrane to enter the blood. Only the hormone precursor cholesterol is stored in significant quantities within steroidogenic cells. Accordingly, the rate of steroid hormone secretion is controlled entirely by the rate of hormone synthesis. In contrast, peptide hormone secretion is controlled primarily by regulating the release of presynthesized stored hormone.

The adrenomedullary catecholamines and thyroid hormone have unique synthetic and secretory pathways; these will be described in Chapter 6.

Dissolving of hydrophilic hormones; transporting of lipophilic hormones

All hormones are carried by the blood, but they are not all transported in the same manner:

- The hydrophilic peptide hormones are transported simply dissolved in the plasma.
- Lipophilic steroids and thyroid hormones cannot dissolve to any extent in the watery plasma; instead, the majority circulate in the blood, bound to plasma proteins. Some are bound to specific plasma proteins designed to carry only one type of hormone, whereas other plasma proteins, such as albumin, indiscriminately pick up any “hitchhiking” hormone.
- Only the small, unbound, freely dissolved fraction of a lipophilic hormone is biologically active (i.e., free to cross capillary walls and bind with target-cell receptors to exert an effect). Once a hormone has interacted with a target cell, it is rapidly inactivated or removed, so it is no longer available to interact with another target cell. Because the carrier-bound hormone is in dynamic equilibrium with the free hormone pool, the bound form of steroid and thyroid hormones provides a large reserve of these lipophilic hormones that can be called on to replenish the active free pool. To maintain normal endocrine function, the magnitude of the small, free, effective pool, rather than the total plasma concentration of a particular lipophilic hormone, is monitored and adjusted.
- Catecholamines are unusual in that only about 50 percent of these hydrophilic hormones circulate as free hormone; the other 50 percent are loosely bound to the plasma protein albumin. Because catecholamines are water soluble, the importance of this protein binding is unclear.

The chemical properties of a hormone dictate not only the means by which blood transports it but also how it can be artificially introduced into the blood for therapeutic purposes. Because the digestive system does not secrete enzymes that can digest steroid and thyroid hormones, when taken orally, these hormones, such as the sex steroids contained

in birth control pills, can be absorbed intact from the digestive tract into the blood. No other type of hormones can be taken orally, because protein-digesting enzymes would attack and convert them into inactive fragments. Therefore, these hormones must be administered by non-oral routes; for example, insulin deficiency is treated with daily injections of insulin.

We now examine how the hydrophilic and lipophilic hormones vary in their mechanisms of action at their target cells.

Hormones and intracellular proteins

To induce their effect, hormones must bind with target-cell receptors specific for them. Each interaction between a particular hormone and a target-cell receptor produces a highly characteristic response that differs among hormones and among different target cells influenced by the same hormone. Both the location of the receptors within the target cell and the mechanism by which binding of the hormone with the receptors induces a response vary, depending on the hormone's solubility characteristics.

LOCATION OF RECEPTORS FOR HYDROPHILIC AND LIPOPHILIC HORMONES

Hormones can be grouped into two categories based on the primary location of their receptors:

1. The hydrophilic peptides and catecholamines, which are poorly soluble in lipid, cannot pass through the lipid membrane barriers of their target cells. Instead, they bind with specific receptors located on the *outer plasma membrane surface* of the target cell.
2. The lipophilic steroids and thyroid hormone easily pass through the surface membrane to bind with specific receptors located *inside* the target cell.

GENERAL MEANS OF HYDROPHILIC AND LIPOPHILIC HORMONE ACTION

Even though hormones elicit a wide variety of biological responses, all hormones ultimately influence their target cells by altering the cell's proteins through three general means:

1. A few hydrophilic hormones, on binding with a target cell's surface receptors, *change the cell's permeability* (either opening or closing channels to one or more ions) by *altering the conformation (shape) of adjacent channel-forming proteins already in the membrane*.
2. Most surface-binding hydrophilic hormones function by *activating second-messenger systems* within the target cell. This activation directly *alters the activity of intracellular target proteins, usually enzymes*, to produce the desired effect.
3. All lipophilic hormones function mainly by *activating specific genes* in the target cell *to cause formation of new intracellular proteins*, which in turn produce the desired effect. The new proteins may be enzymatic or structural.

Let's examine the two major mechanisms of hormonal action (activation of second-messenger systems and activation of genes) in more detail.

Hydrophilic hormones and target proteins

Most hydrophilic hormones (peptides and catecholamines) bind to surface membrane receptors and produce their effects in their target cells by acting through a second-messenger system to alter the activity of preexisting target proteins. There are two major second-messenger pathways: One uses **cyclic adenosine monophosphate (cyclic AMP or cAMP)** as a second messenger, and the other employs calcium in this role.

CYCLIC AMP SECOND-MESSENGER PATHWAY

In the following description of the cAMP pathway, the numbered steps correlate to the numbered steps in ▶ Figure 5-5.

1. Binding of an appropriate extracellular messenger (a first messenger) to its surface membrane receptor eventually activates the enzyme **adenylyl cyclase** (step 1), which is located on the cytoplasmic side of the plasma membrane. A membrane-bound "middleman," a **G protein**, acts as an intermediary between the receptor and adenylyl cyclase. G proteins are found on the inner surface of the plasma membrane. An unactivated G protein consists of a complex of alpha (α), beta (β), and gamma (γ) subunits. A number of different G proteins employing varying subtypes of these subunits have been identified. The different G proteins are activated in response to the binding of various first messengers to surface receptors. When a first messenger binds with its receptor, the receptor attaches to the appropriate G protein, resulting in activation of the α subunit. Once activated, the α subunit breaks away from the G protein complex and moves along the inner surface of the plasma membrane until it reaches an effector protein. An effector protein is either an ion channel or an enzyme within the membrane. The α subunit links up with the effector protein and alters its activity. In the cAMP pathway, adenylyl cyclase is the effector protein that is activated. Researchers have identified more than 300 different receptors that convey instructions of extracellular messengers through the membrane to effector proteins by means of G proteins.
2. Adenylyl cyclase induces the conversion of intracellular ATP to cAMP by cleaving off two of the phosphates (step 2). (This is the same ATP used as the common energy currency in the body.)
3. Acting as the intracellular second messenger, cAMP triggers a preprogrammed series of biochemical steps within the cell to bring about the response dictated by the first messenger. To begin, cyclic AMP activates a specific intracellular enzyme, **protein kinase A** (step 3).
4. Protein kinase A, in turn, phosphorylates (attaches a phosphate group from ATP) a specific intracellular target

► **FIGURE 5-5** Mechanism of action of hydrophilic hormones via activation of the cyclic AMP second-messenger system

protein (step 4), such as an enzyme important in a particular metabolic pathway.

5. Phosphorylation causes the protein to change its shape and function (either activating or inhibiting it) (step 5).

The resultant change is the target cell's ultimate physiological response to the first messenger. For example, the activity of a particular enzymatic protein that regulates a specific metabolic event may be increased or decreased.

After the response is accomplished and the first messenger is removed, the α subunit rejoins the β and γ subunits to restore the inactive G protein complex. Cyclic AMP and the other participating chemicals are inactivated so that the intracellular message is "erased" and the response can be terminated. Otherwise, once triggered, the response would go on indefinitely until the cell ran out of necessary supplies.

Note that in this signal-transduction pathway, the steps involving the extracellular first messenger, the receptor, the G protein complex, and the effector protein occur *in the plasma membrane* and lead to activation of the second messenger. The extracellular messenger cannot gain entry into the cell to "personally" deliver its message to the proteins that carry out the desired response. Instead, it initiates membrane events that activate an intracellular messenger, cAMP. This second messenger then triggers a chain reaction of biochemical events *inside the cell* that leads to the cellular response.

Different types of cells have different pre-existing proteins available for phosphorylation and modification by protein kinase A. Therefore, a *common second messenger, cAMP, can induce widely differing responses in different cells*, depending on what proteins are modified. Cyclic AMP may be viewed as an on-off switch used by many different cells, triggering different cell events depending on the type of protein activity in the target cell. The type of proteins altered by a second messenger depends on the unique specialization of a particular cell type. This can be likened to being able to either illuminate or cool down a room depending on whether the wall switch you flip on is wired to a device specialized to light up (a chandelier) or one specialized to create air movement (a ceiling fan). In the body, the variable responsiveness once the switch is turned on is due to the genetically programmed differences in the sets of proteins within different cells. For example, activating the cAMP system brings about modification of heart rate in the heart, stimulation of the formation of female sex hormones in the ovaries, breakdown of stored glucose in the liver, control of water conservation during urine formation in the kidneys, creation of some simple memory traces in the brain, and perception of a sweet taste by a taste bud.

Check Your Understanding 5.1

1. Compare and contrast the synthesis, storage, secretion, and transport in the blood of peptide hormones and steroid hormones.
2. Explain how a common second messenger such as cAMP can induce widely differing responses in different cells.

CALCIUM SECOND-MESSENGER SYSTEM

Some cells use calcium instead of cAMP as a second messenger. In such cases, binding of the first messenger to the surface receptor eventually leads by means of G proteins to activation of the enzyme **phospholipase C**, a protein effector that is bound to the inner side of the membrane (► Figure 5-6, step 1). This

enzyme breaks down **phosphatidylinositol bisphosphate (PIP₂)**, a component of the tails of the phospholipid molecules within the membrane itself. The products of (PIP₂) breakdown are **diacylglycerol (DAG)** and **inositol trisphosphate (IP₃)** (step 2). (IP₃) is the fragment responsible for mobilizing intracellular Ca²⁺ stores to increase cytosolic Ca²⁺ (step 3a). Calcium then takes over the role of second messenger, ultimately bringing

about the response dictated by the first messenger. Many of the Ca²⁺-dependent cellular events are triggered by activation of **calmodulin**, an intracellular Ca²⁺-binding protein (step 4a). The activated calmodulin complex activates Ca²⁺-calmodulin dependent protein kinase (CaM kinase) (step 5a). Activation of CaM kinase is similar to activation of protein kinase A by cAMP. From here, the patterns of the two pathways are similar, meaning that

FIGURE 5-6 Mechanism of action of hydrophilic hormones via concurrent activation of the (IP₃)-Ca²⁺ second-messenger pathway and the DAG pathway

CaM kinase phosphorylates the inactive target protein (step 6a), which alters its shape and function to either activate or inhibit it. This altered protein brings about the ultimate desired cellular response (step 7a). Simultaneously, the other (PIP₂) breakdown product, DAG, sets off another second-messenger pathway. DAG activates *protein kinase C* (PKC), which in turn brings about a given cellular response by phosphorylating particular cellular proteins (steps 3b–5b).

The cAMP and Ca²⁺ pathways frequently overlap in bringing about a particular cellular activity. For example, cAMP and Ca²⁺ can influence each other. Calcium-activated calmodulin can regulate adenylyl cyclase and thus influence cAMP, whereas protein kinase A may phosphorylate and thereby change the activity of Ca²⁺ channels or carriers.

Although the cAMP and Ca²⁺ pathways are the most prevalent second-messenger systems, they are not the only ones. For example, in a few cells **cyclic guanosine monophosphate (cyclic GMP)** serves as a second messenger in a system analogous to the cAMP system.

Many hydrophilic hormones use cAMP as their second messenger. A few use intracellular Ca²⁺ in this role; for others, the second messenger is still unknown. Remember that activation of second messengers is a universal mechanism employed by a variety of extracellular messengers in addition to hydrophilic hormones.

AMPLIFICATION BY A SECOND-MESSENGER PATHWAY

Amplifiers allow small signals to be converted into much larger signals; second messengers work in a similar fashion through a

cascade of events that amplify the initial stimulus (► Figure 5-7). The binding of one extracellular chemical-messenger molecule to a receptor activates a number of adenylyl cyclase molecules (let us arbitrarily say 10), each of which activates many (in our hypothetical example, let's say 100) cAMP molecules. Each cAMP molecule then acts on a single protein kinase A, which phosphorylates and thereby influences many (again, let us say 100) specific proteins, such as enzymes. Each enzyme, in turn, is responsible for producing many (perhaps 100) molecules of a particular product, such as a secretory product. The result of this cascade of events, with one event triggering the next event in sequence, is a tremendous amplification of the initial signal. In our hypothetical example, one chemical-messenger molecule has been responsible for inducing a yield of 10 million molecules of a secretory product. In this way, very low concentrations of hormones and other chemical messengers can trigger pronounced cell responses.

MODIFICATIONS OF SECOND-MESSENGER PATHWAYS

Although membrane receptors serve as links between extracellular first messengers and intracellular second messengers in the regulation of specific cellular activities, the receptors themselves are also frequently subject to regulation. In many instances, the number and affinity (attraction of a receptor for its chemical messenger) of receptors can be altered, depending on the circumstances. For example, the number of receptors for the hormone insulin can be deliberately decreased in response to a chronic elevation of insulin in the blood. Later, when we cover the specific endocrine glands in detail, you will learn more about this mechanism to regulate the responsiveness of a target cell to its hormone.

► **FIGURE 5-7 Amplification of the initial signal by a second-messenger pathway.** Through amplification, very low concentrations of extracellular chemical messengers, such as hormones, can trigger pronounced cellular responses.

Many disease processes can be linked to malfunctioning receptors or defects in one of the components of the ensuing signal-transduction pathways. For example, defective receptors are responsible for *Laron dwarfism*. In this condition, the person is abnormally short despite having normal levels of growth hormone, because the tissues cannot respond normally to growth hormone. This is in contrast to the more usual type of dwarfism in which the person is abnormally short because of growth hormone deficiency.

Lipophilic hormones and protein synthesis

All lipophilic hormones (steroids and thyroid hormone) bind with intracellular receptors and primarily produce their effects in their target cells by activating specific genes to cause the synthesis of new enzymatic or structural proteins (see Why It Matters). The following steps outline the process, as shown in

► Figure 5-8:

1. Free lipophilic hormone (hormone not bound with its carrier) diffuses through the plasma membrane of the target cell and binds with its specific receptor. Depending on the lipophilic hormone, this receptor is either in the cytoplasm or within the nucleus.
2. Each receptor has a specific region for binding with its hormone and another region for binding with DNA. Once the hormone is bound to the receptor, the hormone receptor complex binds with DNA at a specific attachment site on DNA known as the **hormone response element (HRE)**. Different steroid hormones and thyroid hormone, once bound with their respective receptors, attach at different HREs on DNA. For example, the estrogen receptor complex binds at DNA's estrogen response element.
3. Binding of the hormone receptor complex with DNA ultimately turns on a specific gene within the target cell. This gene contains a code for synthesizing a given protein. The code of the activated gene is transcribed into complementary messenger RNA.
4. The new messenger RNA leaves the nucleus and enters the cytoplasm.
5. In the cytoplasm, messenger RNA binds to a ribosome, the “workbench” that mediates the assembly of new proteins (Appendix C, p. A-21). Here, messenger RNA directs the synthesis of the designated new proteins according to the DNA code in the activated genes.
6. The newly synthesized protein, either enzymatic or structural,

Why It Matters

Lipophilic compounds are significant due to their ability to cross biological membranes. Some of the most highly studied groups of lipophilic compounds are estrogen and estrogen-like (phytoestrogens) compounds. The presence of estrogens in our waste waters has been linked to the disruption of reproduction in several fish species through the feminization of the males. Although this is a specific example using estrogen, similar principles apply to any lipophilic hormone that can persist in the environment. By crossing biological membranes they can activate genes to cause the production of potentially inappropriate proteins and enzymes. The long-term effects on the environment and the human population are largely unknown but are of significant concern.

produces the target cell's ultimate physiological response to the hormone.

By means of this mechanism, different genes are activated by different lipophilic hormones, resulting in different biological effects.

Even though most steroid actions are accomplished by hormonal binding with intracellular receptors that leads to gene activation, recent studies have unveiled another mechanism by which steroid hormones induce effects that occur too rapidly to be mediated by gene transcription. Researchers have learned that some steroid hormones, most notably some of the sex hormones, bind with unique steroid receptors in the plasma membrane, in addition to

► FIGURE 5-8 Activation of genes by lipophilic hormones

binding with the traditional steroid receptors in the nucleus. This membrane binding leads to *nongenomic steroid receptor actions*—that is, actions accomplished by something other than altering gene activity, such as by inducing changes in ionic flux across the membrane or by altering activity of cellular enzymes.

Hormonal responses versus neural responses

Compared with neural responses, which are brought about within milliseconds, hormone action is relatively slow and prolonged; it takes minutes to hours after the hormone binds to its receptor for the response to take place. The variability in time of onset for hormonal responses depends on the mechanism employed. Hormones that act through a second-messenger system to alter a pre-existing enzyme's activity elicit full action within a few minutes. In contrast, hormonal responses that require the synthesis of new protein may take up to several hours before any action is initiated.

As well, in contrast to neural responses, which are quickly terminated once the triggering signal ceases, hormonal responses persist for a period of time after the hormone is no longer bound to its receptor. Once an enzyme is activated in response to hydrophilic hormonal input, it no longer depends on the presence of the hormone. Thus, the response lasts until the enzyme is inactivated. Likewise, once a new protein is synthesized in response to lipophilic hormonal input, it continues to function until it is degraded. As a result, a hormone's effect usually lasts for some time after its withdrawal. Predictably, the responses that depend on protein synthesis last longer than do those stemming from enzyme activation.

Check Your Understanding 5.2

1. Describe the three general mechanisms of controlling hormone secretion that are common to many different hormones.
2. Explain down regulation, permissiveness, synergism, and antagonism.
3. Describe the processes by which lipophilic hormones initiate cellular responses.

5.3 | Comparison of the Nervous and Endocrine Systems

The nervous and endocrine systems are specialized for controlling different types of activities. In general, the nervous system governs the coordination of rapid, precise responses. It is especially important in the body's interactions with the external environment. Neural signals in the form of action potentials are rapidly propagated along nerve cell fibres, resulting in the release at the nerve terminal of a neurotransmitter that has to diffuse only a microscopic distance to its target cell to generate a response. A neurally mediated response is not only rapid but brief; the action is quickly halted as the neurotransmitter is swiftly removed from the target site. This permits either ending the response, almost immediately repeating the response, or

rapidly initiating an alternative response, as circumstances demand (e.g., the swift changes in commands to muscle groups needed to coordinate walking). This mode of action makes neural communication extremely rapid and precise. The target tissues of the nervous system are the muscles and glands, especially exocrine glands, of the body.

The endocrine system, in contrast, is specialized to control activities that require duration rather than speed, such as regulating organic metabolism and water and electrolyte balance; promoting smooth, sequential growth and development; and controlling reproduction. The endocrine system responds more slowly to its triggering stimuli than does the nervous system, for several reasons. First, the endocrine system must depend on blood flow to convey its hormonal messengers over long distances. Second, hormones' mechanisms of action at their target cells typically are more complex than that of neurotransmitters and thus require more time before a response occurs. The ultimate effect of some hormones cannot be detected until a few hours after they bind with target-cell receptors. As well, because of the receptors' high affinities for their respective hormones, hormones often remain bound to receptors for some time, thus prolonging their biological effectiveness. Furthermore, unlike the brief, neurally induced responses that stop almost immediately after the neurotransmitter is removed, endocrine effects usually last for some time after the hormone's withdrawal. Neural responses to a single burst of neurotransmitter release usually last only milliseconds to seconds, whereas the alterations that hormones induce in target cells range from minutes to days or, in the case of growth-promoting effects, even a lifetime. Thus, hormonal action is relatively slow and prolonged, making endocrine control particularly suitable for regulating metabolic activities that require long-term stability.

Although the endocrine and nervous systems have their own areas of specialization, they are intimately interconnected functionally. Some nerve cells do not release neurotransmitters at synapses but instead end at blood vessels and release their chemical messengers (neurohormones) into the blood, where these chemicals act as hormones. A given messenger may even be a neurotransmitter when released from a nerve ending and a hormone when secreted by an endocrine cell. The nervous system directly or indirectly controls the secretion of many hormones (see Chapter 6). At the same time, many hormones act as neuromodulators, altering synaptic effectiveness and thereby influencing the excitability of the nervous system. The presence of certain key hormones is even essential for the proper development and maturation of the brain during fetal life. Furthermore, in many instances the nervous and endocrine systems both influence the same target cells in a supplementary fashion. For example, these two major regulatory systems both help regulate the circulatory and digestive systems. Thus, many important regulatory interfaces exist between the nervous and endocrine systems. The study of these relationships is known as **neuroendocrinology**.

5.4 | The Endocrine Tissues

To this point we have provided an overview of the general principles and functions of the endocrine system. ■ Table 5-3 summarizes the most important specific functions of the

■ **TABLE 5-3** Summary of the Major Hormones

Endocrine Gland	Hormones	Target Cells	Major Functions of Hormones
Hypothalamus	Releasing and inhibiting hormones (TRH, CRH, GnRH, GHRH, GHIH, PRH, PIH)	Anterior pituitary	Controls release of anterior pituitary hormones
Posterior Pituitary (hormones stored in)	Vasopressin	Kidney tubules	Increases H ₂ O reabsorption
	Oxytocin	Arterioles	Produces vasoconstriction
		Uterus	Increases contractility
Mammary glands (breasts)		Causes milk ejection	
Anterior Pituitary	Thyroid-stimulating hormone (TSH)	Thyroid follicular cells	Stimulates T ₃ and T ₄ secretion
	Adrenocorticotrophic hormone (ACTH)	Zona fasciculata and zona reticularis of adrenal cortex	Stimulates cortisol secretion
	Growth hormone	Bone; soft tissues	Essential but not solely responsible for growth; stimulates growth of bones and soft tissues; metabolic effects include protein anabolism, fat mobilization, and glucose conservation
	Follicle-stimulating hormone (FSH)	Liver	Stimulates somatomedin secretion
		<i>Females</i> : ovarian follicles	Promotes follicular growth and development; stimulates estrogen secretion
		<i>Males</i> : seminiferous tubules in testes	Stimulates sperm production
	Luteinizing hormone (LH) (interstitial cell-stimulating hormone—ICSH)	<i>Females</i> : ovarian follicle and corpus luteum	Stimulates ovulation, corpus luteum development, and estrogen and progesterone secretion
		<i>Males</i> : interstitial cells of Leydig in testes	Stimulates testosterone secretion
	Prolactin	<i>Females</i> : mammary glands	Promotes breast development; stimulates milk secretion
		<i>Males</i>	Uncertain
Pineal Gland	Melatonin	Brain; anterior pituitary; reproductive organs; immune system; possibly other systems	Entrains body's biological rhythm with external cues; inhibits gonadotropins; its reduction likely initiates puberty; acts as an antioxidant; enhances immunity
Thyroid Gland	Tetraiodothyronine (T ₄ or thyroxine); triiodothyronine (T ₃)	Most cells	Increases the metabolic rate; essential for normal growth and nerve development
Thyroid Gland C Cells	Calcitonin	Bone	Decreases plasma Ca ²⁺ concentration
Adrenal Cortex			
<i>Zona glomerulosa</i>	Aldosterone (mineralocorticoid)	Kidney tubules	Increases Na ⁺ reabsorption and K ⁺ secretion
<i>Zona fasciculata and zona reticularis</i>	Cortisol (glucocorticoid)	Most cells	Increases blood glucose at the expense of protein and fat stores; contributes to stress adaption
	Androgens (dehydroepiandrosterone)	<i>Females</i> : bone and brain	Responsible for the pubertal growth spurt and sex drive in females

(continued)

TABLE 5-3 Summary of the Major Hormones (continued)

Endocrine Gland	Hormones	Target Cells	Major Functions of Hormones
Adrenal Medulla	Epinephrine and norepinephrine	Sympathetic receptor sites throughout the body	Reinforces the sympathetic nervous system; contributes to stress adaptation and blood pressure regulation
Endocrine Pancreas (Islets of Langerhans)	Insulin (β cells)	Most cells	Promotes cellular uptake, use, and storage of absorbed nutrients
	Glucagon (α cells)	Most cells	Important for maintaining nutrient levels in blood during postabsorptive state
	Somatostatin (D cells)	Digestive system Pancreatic islet cells	Inhibits digestion and absorption of nutrients Inhibits secretion of all pancreatic hormones
Parathyroid Gland	Parathyroid hormone (PTH)	Bone, kidneys, intestine	Increases plasma Ca^{2+} concentration; decreases plasma PO_4^{3-} concentration; stimulates vitamin D activation
Gonads			
<i>Female: ovaries</i>	Estrogen (estradiol)	Female sex organs; body as a whole	Promotes follicular development; governs development of secondary sexual characteristics; stimulates uterine and breast growth
		Bone	Promotes closure of the epiphyseal plate
	Progesterone	Uterus	Prepares for pregnancy
<i>Male: testes</i>	Testosterone	Male sex organs; body as a whole	Stimulates sperm production; governs development of secondary sexual characteristics; promotes sex drive
		Bone	Enhances pubertal growth spurt; promotes closure of the epiphyseal plate
<i>Testes and ovaries</i>	Inhibin	Anterior pituitary	Inhibits secretion of follicle-stimulating hormone
Placenta	Estrogen (estriol); progesterone	Female sex organs	Help maintain pregnancy; prepare breasts for lactation
	Chorionic gonadotropin	Ovarian corpus luteum	Maintains corpus luteum of pregnancy
Kidneys	Renin ($\rightarrow$ angiotensin)	Zona glomerulosa of adrenal cortex (acted on by angiotensin, which is activated by renin)	Stimulates aldosterone secretion
Stomach	Erythropoietin	Bone marrow	Stimulates erythrocyte production
	Gastrin	Digestive tract exocrine glands and smooth muscles; pancreas; liver; gallbladder	Controls motility and secretion to facilitate digestive and absorptive processes
Duodenum	Secretin; cholecystokinin		
	Glucose-dependent insulinotropic peptide	Endocrine pancreas	Stimulates insulin secretion
Liver	Somatomedins (insulin-like growth factors [IGF])	Bone; soft tissues	Promotes growth
Skin	Vitamin D	Intestine	Increases absorption of ingested Ca^{2+} and PO_4^{3-}
Thymus	Thymosin	T lymphocytes	Enhances T lymphocyte proliferation and function
Heart	Atrial natriuretic peptide	Kidney tubules	Inhibits Na^+ reabsorption
Adipose Tissue	Leptin	Hypothalamus	Suppresses appetite; important in long-term control of body weight
	Other adipokines	Multiple sites	Play role in metabolism and inflammation

major hormones for both the central and the peripheral endocrine glands. As extensive as ■ Table 5.3 appears, it leaves out a variety of potential hormones that have not yet been fully recognized as hormones, either because they do not quite fit the classic definition of a hormone or because they have been discovered so recently that their hormonal status has not yet been conclusively documented. The table also excludes the cytokines secreted by the effector cells of the defence system (white blood cells and macrophages; p. 485) and a variety of recently revealed and poorly understood growth factors that promote growth of specific tissues, such as *epidermal growth factor* and *nerve growth factor*. Furthermore, new hormones are likely to be discovered, and additional functions may be found for known hormones. As an example, vasopressin's role in conserving water during urine formation was determined first, followed later by the discovery of its constrictor effect on arterioles. More recently, vasopressin has also been found to play roles in fever, learning, memory, and behaviour.

Some of the hormones listed in the table are not discussed further in this chapter but are described in other chapters, as follows: the renal hormones (erythropoietin in Chapter 10 and renin in Chapter 13), thrombopoietin from the liver (Chapter 10), the gastrointestinal hormones (Chapter 15), thymosin from the thymus (Chapter 11), atrial natriuretic peptide from the heart (Chapter 13), and leptin and other adipokines from adipose tissue (Chapter 16). The remainder of the hormones are

described in detail in the following sections of this chapter and in Chapter 6, where the peripheral endocrine glands are discussed.

We now focus on the central endocrine glands—those in the brain itself or in close association with the brain—namely, the hypothalamus, the pituitary gland, and the pineal gland.

5.5 | Hypothalamus and Pituitary

The **pituitary gland (hypophysis)** (1 cm in diameter, 1 g in weight) is a small endocrine gland located in a bony cavity at the base of the brain just below the hypothalamus (► Figure 5-9). The pituitary is connected to the hypothalamus by a thin connecting stalk. If you point one finger between your eyes and another finger toward one of your ears, the imaginary point where these lines would intersect is about where your pituitary is located.

The anterior and posterior glands

The pituitary has two anatomically and functionally distinct lobes, the **posterior pituitary gland** and the **anterior pituitary gland**. The posterior pituitary is composed of nervous tissue and thus is also termed the **neurohypophysis**. The anterior pituitary consists of glandular epithelial tissue and accordingly is called

► **FIGURE 5-9 Anatomy of the pituitary gland.** (a) Relation of the pituitary gland to the hypothalamus and to the rest of the brain. (b) Schematic enlargement of the pituitary gland and its connection to the hypothalamus

the **adenohypophysis** (*adeno* means “glandular”). The anterior and posterior pituitary have only their location in common.

In some species, the adenohypophysis also includes a third, well-defined *intermediate lobe*, but humans lack this lobe. In lower vertebrates, the intermediate lobe secretes several **melanocyte-stimulating hormones (MSH)**, which regulate skin colouration by controlling the dispersion of granules that contain the pigment **melanin** (p. 462). By causing variable skin darkening in certain amphibians, reptiles, and fishes, MSH plays a vital role in the camouflage of these species.

In humans, a part of the anterior pituitary that briefly exists as a separate intermediate lobe during fetal development secretes a small amount of MSH. However, although excessive MSH activity does darken skin, MSH is not involved in differences in skin colouration associated with the amount of melanin deposited in the skin nor in the process of skin tanning. Instead, MSH in humans plays a totally different role in helping control food intake. It also appears to influence excitability of the nervous system, perhaps improving memory and learning. Also, MSH has been shown to suppress the immune system, perhaps helping to serve in some way as a check-and-balance that prevents excessive immune responses.

The hypothalamus and posterior pituitary

The release of hormones from both the posterior and the anterior pituitary is directly controlled by the hypothalamus. However, the nature of the relationship between the hypothalamus and each of these parts of the pituitary is entirely different. The posterior pituitary connects to the hypothalamus by a neural pathway, whereas the anterior pituitary connects to the hypothalamus by a unique vascular link. First, let's look at the posterior pituitary.

The hypothalamus and posterior pituitary form a neuroendocrine system that consists of a population of neurosecretory neurons whose cell bodies lie in two well-defined clusters in the hypothalamus (the **supraoptic nuclei** and **paraventricular nuclei**). The axons of these neurons pass down through the thin connecting stalk and terminate on capillaries in the posterior pituitary (▶ Figure 5-10). The posterior pituitary consists of these neuronal terminals plus glial-like supporting cells. Functionally as well as anatomically, the posterior pituitary is simply an extension of the hypothalamus.

The posterior pituitary does not actually produce any hormones. It simply stores and, on appropriate stimulation, releases into the blood two small peptide hormones, *vasopressin* and *oxytocin*, which are synthesized by the neuronal cell bodies in the hypothalamus. These hydrophilic peptides are made in both the supraoptic and the paraventricular nuclei, but a single neuron can produce only one of these hormones. The synthesized hormones are packaged in secretory granules that are transported down the cytoplasm of the axon and stored in the neuronal terminals within the posterior pituitary. Each terminal stores either vasopressin or oxytocin, but not both. Thus, these hormones can be released independently as needed. On stimulatory input to the hypothalamus, either vasopressin or oxytocin is released into the systemic blood from the posterior pituitary by exocytosis of the appropriate secretory granules. This hormonal release is

1 The paraventricular and supraoptic nuclei both contain neurons that produce vasopressin and oxytocin. The hormone, either vasopressin or oxytocin depending on the neuron, is synthesized in the neuronal cell body in the hypothalamus.

2 The hormone travels down the axon to be stored in the neuronal terminals within the posterior pituitary.

3 When the neuron is excited, the stored hormone is released from the terminals into the systemic blood for distribution throughout the body.

▶ **FIGURE 5-10** Relationship of the hypothalamus and posterior pituitary

triggered in response to action potentials that originate in the hypothalamic cell body and sweep down the axon to the neuronal terminal in the posterior pituitary. As in any other neuron, action potentials are generated in these neurosecretory neurons in response to synaptic input to their cell bodies.

Relationship of the hypothalamus and posterior pituitary

The actions of vasopressin and oxytocin are summarized here and more thoroughly described in later chapters—vasopressin in Chapters 13 and 14 and oxytocin in Chapter 17.

VASOPRESSIN

Vasopressin (antidiuretic hormone, ADH) has two major effects that correspond to its two names: (1) it enhances the retention of water by the kidneys (an antidiuretic effect), and (2) it causes contraction of arteriolar smooth muscle (a vessel pressor effect). The first effect has more physiological importance. Under normal conditions, vasopressin is the primary endocrine factor that regulates urinary water loss and overall water balance. When vasopressin is absent from the collecting tubes and ducts, very little water is reabsorbed and the loss of water in the urine is substantially greater. In contrast, typical levels of vasopressin play only a minor role in regulating blood pressure by means of the hormone's pressor effect.

The major control for hypothalamic-induced release of vasopressin from the posterior pituitary is input from hypothalamic osmoreceptors, which increase vasopressin secretion in response to a rise in plasma osmolarity. However, the exact mechanism through which the osmotic concentration of ECF controls the release of vasopressin is unclear. A less powerful input from the left atrial volume receptors increases vasopressin secretion in response to a fall in ECF volume and arterial blood pressure (p. 617).

OXYTOCIN

Oxytocin stimulates contraction of the uterine smooth muscle to help expel the infant during childbirth, and it promotes ejection of the milk from the mammary glands (breasts) during breastfeeding. Appropriately, oxytocin secretion is increased by reflexes that originate within the birth canal during childbirth and by reflexes that are triggered when the infant suckles the breast. Oxytocin is important to the birthing process. Animal studies have demonstrated that if oxytocin is removed during the latter part of gestation, labour becomes prolonged.

In addition to these two major physiological effects, oxytocin has recently been shown to influence a variety of behaviours, especially maternal behaviours. For example, this hormone fittingly facilitates bonding, or attachment, between a mother and her infant.

Anterior pituitary hormones: Mostly tropic

Unlike the posterior pituitary, which releases hormones synthesized by the hypothalamus, the anterior pituitary itself synthesizes the hormones it releases into the blood. Different cell populations within the anterior pituitary secrete six major peptide hormones. The actions of each of these hormones are described in detail in later sections. For now, here is a brief statement of their primary effects to provide a rationale for their names ► (Figure 5-11):

1. **Growth hormone (GH, somatotropin)**, the primary hormone responsible for regulating overall body growth, is also important in intermediary metabolism.

2. **Thyroid-stimulating hormone (TSH, thyrotropin)** stimulates secretion of thyroid hormone and growth of the thyroid gland.

3. **Adrenocorticotrophic hormone (ACTH, adrenocorticotropin)** stimulates cortisol secretion by the adrenal cortex and promotes growth of the adrenal cortex.

4. **Follicle-stimulating hormone (FSH)** in females stimulates growth and development of ovarian follicles, within which the ova, or eggs, develop. It also promotes secretion of the hormone estrogen by the ovaries. In males, FSH is required for sperm production.

5. **Luteinizing hormone (LH)** in females is responsible for ovulation and luteinization (i.e., the formation of a hormone-secreting corpus luteum in the ovary following ovulation). LH also regulates ovarian secretion of the female sex hormones, estrogen and progesterone. In males, the same hormone stimulates the interstitial cells of Leydig in the testes to secrete the male sex hormone, testosterone, giving rise to its alternative name of **interstitial cell-stimulating hormone (ICSH)**.

6. **Prolactin (PRL)** enhances breast development and milk production in females. Its function in males is uncertain, although evidence indicates that it may induce the production of testicular LH receptors. Furthermore, recent studies suggest that prolactin may enhance the immune system and support the development of new blood vessels at the tissue level in both sexes—both actions totally unrelated to its known roles in reproductive physiology.

TSH, ACTH, FSH, and LH are all tropic hormones, because they each regulate the secretion of another specific endocrine gland. FSH and LH are collectively referred to as **gonadotropins** because they control secretion of the sex hormones by the gonads (ovaries and testes). Because growth hormone exerts its growth-promoting effects indirectly by stimulating the release of liver hormones, the *somatomedins*, it too is sometimes categorized as a tropic hormone. Among the anterior pituitary hormones, prolactin is the only one that does not stimulate secretion of another hormone. Of the tropic hormones, FSH, LH, and growth hormone exert effects on nonendocrine target cells in addition to stimulating secretion of other hormones.

Hypothalamic releasing and inhibiting hormones

None of the anterior pituitary hormones are secreted at a constant rate. Even though each of these hormones has a unique control system, there are some common regulatory patterns. The two most important factors that regulate anterior pituitary hormone secretion are (1) hypothalamic hormones and (2) feedback by target-gland hormones.

Because the anterior pituitary secretes hormones that control the secretion of various other hormones, it long held the undeserved title of “master gland.” Scientists now know that the release of each anterior pituitary hormone is largely controlled by still other hormones produced by the hypothalamus.

© 2016 Cengage

► **FIGURE 5-11 Functions of the anterior pituitary hormones.** Five different endocrine cell types produce the six anterior pituitary hormones—TSH, ACTH, growth hormone, LH and FSH (produced by the same cell type), and prolactin—which exert a wide range of effects throughout the body.

The secretion of these regulatory neurohormones, in turn, is controlled by a variety of neural and hormonal inputs to the hypothalamic neurosecretory cells.

ROLE OF THE HYPOTHALAMIC RELEASING AND INHIBITING HORMONES

The secretion of each anterior pituitary hormone is stimulated or inhibited by one or more of the seven hypothalamic **hypophysiotropic hormones** (*hypophysis* means “pituitary”; *tropic* means “nourishing”). These small peptide hormones are listed in ■ Table 5-4. Depending on their actions, these hormones are called **releasing hormones** or **inhibiting hormones**. In each case, the primary action of the hormone is apparent from its name. For example, **thyrotropin-releasing hormone (TRH)** stimulates the release of TSH (alias thyrotropin) from the anterior pituitary, whereas **prolactin-inhibiting hormone (PIH)** inhibits the release of prolactin from the anterior pituitary. Note that hypophysiotropic hormones in most cases are involved in a three-hormone hierarchic chain of command (► Figure 5-12): The hypothalamic hypophysiotropic hormone (*hormone 1*) controls the output of an anterior pituitary tropic hormone (*hormone 2*). This tropic hormone, in turn, regulates secretion of the target endocrine gland’s hormone (*hormone 3*), which exerts the final physiological effect.

Although endocrinologists originally speculated that there was one hypophysiotropic hormone for each anterior pituitary hormone, many hypothalamic hormones have more than one effect, so their names indicate only the function first identified. Moreover, a single anterior pituitary hormone may be regulated by two or more hypophysiotropic hormones, which may even exert opposing effects. For example, **growth hormone–releasing hormone (GHRH)** stimulates growth hormone secretion, whereas **growth hormone–inhibiting hormone (GHIH)**, also known as **somatostatin**, inhibits it. The output of the anterior pituitary growth hormone–secreting cells (i.e., the rate of growth hormone secretion) in response to two such opposing inputs depends on the relative concentrations of these hypothalamic hormones as well as on the intensity of other regulatory inputs.

Chemical messengers that are identical in structure to the hypothalamic releasing and inhibiting hormones and to vasopressin are produced in many areas of the brain outside the hypothalamus. Instead of being released into the blood, these messengers act locally as neurotransmitters and as neuromodulators in these other sites. For example, PIH is identical to *dopamine*, a major neurotransmitter in the basal nuclei and elsewhere (p. 124). Others are thought to modulate a variety of functions that range from motor activity (TRH) to libido (GnRH) to learning (vasopressin). These examples further illustrate the multiplicity of ways chemical messengers function.

ROLE OF THE HYPOTHALAMIC-HYPOPHYSEAL PORTAL SYSTEM

The hypothalamic regulatory hormones reach the anterior pituitary by means of a unique vascular link. In contrast to the direct neural connection between the hypothalamus and posterior pituitary, the anatomic and functional link between the hypothalamus and anterior pituitary is an unusual capillary-to-capillary

■ **TABLE 5-4 Major Hypophysiotropic Hormones**

Hormone	Effect on the Anterior Pituitary
Thyrotropin-Releasing Hormone (TRH)	Stimulates release of TSH (thyrotropin) and prolactin
Corticotropin-Releasing Hormone (CRH)	Stimulates release of ACTH (corticotropin)
Gonadotropin-Releasing Hormone (GnRH)	Stimulates release of FSH and LH (gonadotropins)
Growth Hormone–Releasing Hormone (GHRH)	Stimulates release of growth hormone
Growth Hormone–Inhibiting Hormone (GHIH)	Inhibits release of growth hormone and TSH
Prolactin-Releasing Hormone (PRH)	Stimulates release of prolactin
Prolactin-Inhibiting Hormone (PIH)	Inhibits release of prolactin

connection: the **hypothalamic-hypophyseal portal system**.

A portal system is a vascular arrangement in which blood flows directly from one capillary bed through a connecting vessel to another capillary bed. The largest and best-known portal system is the hepatic portal system, which drains intestinal blood directly into the liver for immediate processing of absorbed nutrients (p. 671). Although much smaller, the hypothalamic-hypophyseal portal system is no less important, because it provides a critical link between the brain and much of the endocrine system. It begins in the base of the hypothalamus with a group of capillaries that recombine into small portal vessels, which pass down through the connecting stalk into the anterior pituitary. Here, the portal vessels branch to form most of the anterior pituitary capillaries, which in turn drain into the systemic system (► Figure 5-13).

As a result, almost all the blood supplied to the anterior pituitary must first pass through the hypothalamus. Because materials can be exchanged between the blood and surrounding tissue only at the capillary level, the hypothalamic-hypophyseal portal system provides a route where the releasing and inhibiting hormones can be picked up at the hypothalamus and delivered immediately and directly to the anterior pituitary at relatively high concentrations, completely bypassing the general circulation. If the portal system did not exist, once the hypophysiotropic hormones were picked up in the hypothalamus, they would be returned to the heart by the systemic venous system. From here, they would travel to the lungs and back to the heart through the pulmonary circulation, and finally enter the systemic arterial system for delivery throughout the body, including the anterior pituitary. This process would not only take longer, but the

© 2016 Cengage

► **FIGURE 5-12 Hierarchic chain of command and negative feedback in endocrine control.** The general pathway involved in the hierarchic chain of command among the hypothalamus, anterior pituitary, and peripheral target endocrine gland is depicted on the left. The pathway on the right leading to cortisol secretion provides a specific example of this endocrine chain of command. The hormone ultimately secreted by the target endocrine gland, such as cortisol, acts in negative-feedback fashion to reduce secretion of the regulatory hormones higher in the chain of command.

hypophysiotropic hormones would be considerably diluted by the much larger volume of blood flowing through this usual circulatory route.

The axons of the neurosecretory neurons that produce the hypothalamic regulatory hormones terminate on the capillaries at the origin of the portal system. These hypothalamic neurons

secrete their hormones in the same way as the hypothalamic neurons that produce vasopressin and oxytocin. The hormone is synthesized in the cell body and then transported to the axon terminal. It is stored there until its release into an adjacent capillary on appropriate stimulation. The major difference is that the hypophysiotropic hormones are released into the portal vessels, which deliver them to the anterior pituitary, where they control the release of anterior pituitary hormones into the general circulation. In contrast, the hypothalamic hormones stored in the posterior pituitary are themselves released into the general circulation.

CONTROL OF HYPOTHALAMIC RELEASING AND INHIBITING HORMONES

What regulates secretion of these hypophysiotropic hormones? As in other neurons, the neurons secreting these regulatory hormones receive abundant input of information (both neural and hormonal and both excitatory and inhibitory) that they must integrate. Studies are still in progress to unravel the complex neural input from many diverse areas of the brain to the hypophysiotropic secretory neurons. Some of these inputs carry information about a variety of environmental conditions. One example is the marked increase in secretion of corticotropin-releasing hormone (CRH) in response to stress (see ► Figure 5-12). Numerous neural connections also exist between the hypothalamus and the portions of the brain concerned with emotions (the limbic system; p. 124). Thus, emotions greatly influence secretion of hypophysiotropic hormones. Menstrual irregularities sometimes experienced by women who are emotionally upset are a common manifestation of this relationship.

In addition to being regulated by different regions of the brain, the hypophysiotropic neurons are controlled by various chemical inputs that reach the hypothalamus through the blood. Unlike other regions of the brain, portions of the hypothalamus are not guarded by the blood-brain barrier, so the hypothalamus can easily monitor chemical changes in the blood. The most common blood-borne factors that influence hypothalamic neurosecretion are the target-gland hormones that produce negative-feedback effects, to which we now turn our attention.

Target-gland hormones

In most cases, hypophysiotropic hormones initiate a three-hormone sequence: (1) hypophysiotropic hormone, (2) anterior pituitary tropic hormone, and (3) hormone from the peripheral target endocrine gland. Typically, in addition to producing its physiological effects, the target-gland hormone suppresses secretion of the tropic hormone that is driving its secretion. This negative feedback is accomplished by the target-gland hormone acting either directly on the pituitary itself or on the release of hypothalamic hormones, which in turn regulate anterior pituitary function (see ► Figure 5-12). As an example,

1 Hypophysiotropic hormones (releasing hormones and inhibiting hormones) produced by neurosecretory neurons in the hypothalamus enter the hypothalamic capillaries.

2 These hypothalamic capillaries rejoin to form the hypothalamic-hypophyseal portal system, a vascular link to the anterior pituitary.

3 The portal system branches into the capillaries of the anterior pituitary.

4 The hypophysiotropic hormones, which leave the blood across the anterior pituitary capillaries, control the release of anterior pituitary hormones.

5 When stimulated by the appropriate hypothalamic releasing hormone, the anterior pituitary secretes a given hormone into these capillaries.

6 The anterior pituitary capillaries rejoin to form a vein, through which the anterior pituitary hormones leave for ultimate distribution throughout the body by the systemic circulation.

► **FIGURE 5-13** Vascular link between the hypothalamus and anterior pituitary

consider the CRH–ACTH–cortisol system. Hypothalamic CRH (corticotropin-releasing hormone) stimulates the anterior pituitary to secrete ACTH (adrenocorticotrophic hormone, alias corticotropin), which in turn stimulates the adrenal cortex to secrete cortisol. The final hormone in the system, cortisol, inhibits CRH secretion from the hypothalamus and also reduces the sensitivity of the ACTH-secreting cells to CRH by acting directly on the anterior pituitary. Through this double-barrelled approach, cortisol exerts negative-feedback control to stabilize its own plasma concentration. If plasma cortisol levels start to rise above a prescribed set level, cortisol suppresses its own further secretion by its inhibitory actions at the hypothalamus and anterior pituitary. This mechanism ensures that once a hormonal system is activated, its secretion does not continue unabated. If plasma cortisol levels fall below the desired set point, cortisol's inhibitory actions at the hypothalamus and anterior pituitary are reduced, so the driving forces for cortisol secretion (CRH–ACTH) increase accordingly. The other target-gland hormones act by similar negative-feedback loops to keep their plasma levels relatively constant at the set point.

Diurnal rhythms are superimposed on this type of stabilizing negative-feedback regulation; that is, the set point changes as a function of the time of day. Furthermore, other controlling inputs may break through the negative-feedback control to alter hormone secretion (i.e., change the set level) at times of special need. For example, stress raises the set point for cortisol secretion.

The detailed functions and control of all the anterior pituitary hormones except growth hormone are discussed in other chapters in conjunction with the target tissues that they

influence. For example, thyroid-stimulating hormone is covered in Chapter 6 with the discussion of the thyroid gland. Accordingly, growth hormone is the only anterior pituitary hormone we elaborate on at this time.

Check Your Understanding 5.3

1. Draw a flow diagram showing the hierarchic chain of command and negative feedback in the hypothalamic–anterior pituitary–peripheral target endocrine-gland axis.
2. List the posterior pituitary hormones, the anterior pituitary hormones, and the hypophysiotropic hormones.
3. Compare the means by which the hypothalamus controls hormonal output from the posterior pituitary and from the anterior pituitary.

5.6 | Endocrine Control of Growth

In growing children, continuous net protein synthesis occurs under the influence of growth hormone as the body steadily gets larger. Weight gain alone is not synonymous with growth, because weight gain may occur from retaining excess water or storing fat without true structural growth of tissues. Growth requires net synthesis of proteins and includes lengthening of the long bones (the bones of the extremities) as well as increases in the size and number of cells in the soft tissues.

Growth hormone

Although, as the name implies, growth hormone (GH) is absolutely essential for growth, it is not wholly responsible for determining the rate and final magnitude of growth in a given individual. The following factors affect growth:

- *Genetic determination* of an individual's maximum growth capacity. Attaining this full growth potential further depends on the other factors listed here.
- *An adequate diet*, including enough total protein and ample essential amino acids to accomplish the protein synthesis necessary for growth. Malnourished children never achieve their full growth potential. The growth-stunting effects of inadequate nutrition are most profound when they occur in infancy. In severe cases, the child may be locked into irreversibly stunted body growth and brain development. About 70 percent of total brain growth occurs in the first two years of life. By contrast, a person cannot exceed his or her genetically determined maximum by eating a more than adequate diet. The excess food intake produces obesity instead of growth.
- *Freedom from chronic disease and stressful environmental conditions*. Stunted growth under adverse circumstances is due in large part to the prolonged stress-induced secretion of cortisol from the adrenal cortex. Cortisol exerts several potent antigrowth effects, such as promoting protein breakdown, inhibiting growth in the long bones, and blocking the secretion of GH. Even though sickly or stressed children do not grow well, if the underlying condition is corrected before adult size is achieved, they can rapidly catch up to their normal growth curve through a remarkable spurt in growth.
- *Normal levels of growth-influencing hormones*. In addition to the absolutely essential GH, other hormones—including thyroid hormone, insulin, and the sex hormones—play secondary roles in promoting growth.

The rate of growth is not continuous, neither are the factors responsible for promoting growth the same throughout the growth period. *Fetal growth* is promoted largely by certain hormones from the placenta (the hormone-secreting organ of exchange between the fetal and maternal circulatory systems; p. 760), with the size at birth being determined principally by genetic and environmental factors. GH plays no role in fetal development. After birth, GH and other nonplacental hormonal factors begin to play an important role in regulating growth. Genetic and nutritional factors also strongly affect growth during this period.

Children display two periods of rapid growth—a *postnatal growth spurt* during their first two years of life and a *pubertal growth spurt* during adolescence (► Figure 5-14). From age 2 until puberty, the *rate* of linear growth progressively declines, even though the child is still growing. Before puberty there is little sexual difference in height or weight. During puberty, a marked acceleration in linear growth takes place because the long bones lengthen. Puberty begins at about age 11 in girls and

13 in boys and lasts for several years in both sexes. The mechanisms responsible for the pubertal growth spurt are not clearly understood. Apparently both genetic and hormonal factors are involved. Some evidence indicates that GH secretion is elevated during puberty and thus may contribute to growth acceleration during this time. Furthermore, **androgens** (male sex hormones), whose secretion increases dramatically at puberty, also contribute to the pubertal growth spurt by promoting protein synthesis and bone growth. The potent androgen from the male testes, testosterone, is of greatest importance in promoting a sharp increase in height in adolescent boys. The less potent adrenal androgens from the adrenal gland, which also show a sizable increase in secretion during adolescence, are most likely important in the female pubertal growth spurt. Although estrogen secretion by the ovaries also begins during puberty, it is unclear what role this female sex hormone may play in the pubertal growth spurt in girls. Testosterone and estrogen both ultimately act on bone to halt its further growth so that full adult height is attained by the end of adolescence.

As previously discussed, pituitary hormones primarily regulate the function of the target cells (glands). However, the exception to this rule is growth hormone, which exerts its effects on most tissues of the body. GH is the most abundant hormone produced by the anterior pituitary, even in adults in whom growth has already ceased, although GH secretion typically starts to decline after middle age. The continued high secretion of GH beyond the growing period implies that this hormone has important influences other than on growth. In addition to promoting growth, GH has important metabolic effects and enhances the immune system. We will briefly describe GH's metabolic actions before turning our attention to its growth-promoting actions.

METABOLIC ACTIONS OF GH UNRELATED TO GROWTH

The specific metabolic effects of growth hormone are (1) increased rate of protein synthesis in all body cells, (2) increased fatty acid mobilization from adipose tissue and increased fatty acid use by body tissues, and (3) decreased

► FIGURE 5-14 Normal growth curve

rate of glucose/glycogen use by body tissues. Thus, the overall metabolic effect of GH is to mobilize fat stores as a major energy source while conserving glucose for glucose-dependent tissues, such as the brain. This metabolic pattern is suitable for maintaining the body during prolonged fasting or other situations when the body's energy needs exceed available glucose stores.

GROWTH-PROMOTING ACTIONS OF GH ON SOFT TISSUES

When tissues are responsive to its growth-promoting effects, GH stimulates growth of both soft tissues and the skeleton. GH promotes growth of soft tissues by (1) increasing the number of cells (**hyperplasia**) and (2) increasing the size of cells (**hypertrophy**). GH increases the number of cells by stimulating cell division and by preventing apoptosis (programmed cell death; p. 114). GH increases the size of cells by favouring synthesis of proteins, the main structural component of cells. GH stimulates almost all aspects of protein synthesis while it simultaneously inhibits protein degradation. It promotes the uptake of amino acids (the raw materials for protein synthesis) by cells, decreasing blood amino acid levels in the process. Furthermore, it stimulates the cellular machinery responsible for accomplishing protein synthesis according to the cell's genetic code.

Growth of the long bones resulting in increased height is the most dramatic effect of GH. Before you can understand the means by which GH stimulates bone growth, you must first become familiar with the structure of bone and how growth of bone is accomplished.

Bone thickness and length

Bone is a living tissue. As a form of connective tissue, it consists of cells and an extracellular organic matrix produced by the cells. Bone also has a high degree of vascularization, which allows delivery of nutrients hormones. The bone cells that produce the organic matrix are known as **osteoblasts** (bone formers). Osseous tissue is the primary tissue of bone, a lightweight composite material made primarily of *calcium phosphate*. It is the osseous tissue that gives bone its rigidity and compressive strength. Although bones are relatively brittle, they do have a high degree of elasticity that is provided by collagen (p. 34). If bones consisted entirely of inorganic crystals, they would be brittle, like pieces of chalk. Bones have structural strength approaching that of reinforced concrete, yet they are not brittle and are much lighter in weight, because they have the structural blending of an organic scaffolding hardened by inorganic crystals. **Cartilage** is similar to bone, except that living cartilage is not calcified.

A long bone basically consists of a fairly uniform cylindrical shaft, the **diaphysis**, with a flared articulating knob at either end, an **epiphysis**. In a growing bone, the diaphysis is separated at each end from the epiphysis by a layer of cartilage known as the **epiphyseal plate** (► Figure 5-15a). The central cavity of the bone is filled with bone marrow, the site of blood cell production.

BONE GROWTH

Growth in *thickness* of bone is achieved by adding new bone on top of the outer surface of already existing bone. This growth is produced by osteoblasts within the **periosteum**, a connective tissue sheath that covers the outer bone. As osteoblasts deposit new bone on the external surface, other cells within the bone, the **osteoclasts** (bone breakers), dissolve the bony tissue on the inner surface next to the marrow cavity. In this way, the marrow cavity enlarges to keep pace with the increased circumference of the bone shaft.

Growth in *length* of long bones is accomplished by a different mechanism. Bones grow in length as a result of activity of the cartilage cells, or **chondrocytes**, in the epiphyseal plates (► Figure 5-15b). During growth, cartilage cells on the outer edge of the plate next to the epiphysis divide and multiply, temporarily widening the epiphyseal plate. As new chondrocytes are formed on the epiphyseal border, the older cartilage cells toward the diaphyseal border are enlarging. This combination of proliferation of new cartilage cells and hypertrophy of maturing chondrocytes temporarily widens the epiphyseal plate. This thickening of the intervening cartilaginous plate pushes the bony epiphysis farther away from the diaphysis. Soon the matrix surrounding the oldest hypertrophied cartilage becomes calcified. Because cartilage lacks its own capillary network, the survival of cartilage cells depends on diffusion of nutrients and oxygen through the matrix, a process prevented by the deposition of calcium salts. As a result, the old nutrient-deprived cartilage cells on the diaphyseal border die. As osteoclasts clear away dead chondrocytes and the calcified matrix that imprisoned them, the area is invaded by osteoblasts, which swarm upward from the diaphysis, trailing their capillary supply with them. These new “tenants” lay down bone around the persisting remnants of disintegrated cartilage until bone entirely replaces the inner region of cartilage on the diaphyseal side of the plate. When this **ossification** (bone formation) is complete, the bone on the diaphyseal side has lengthened and the epiphyseal plate has returned to its original thickness. The cartilage that bone has replaced on the diaphyseal end of the plate is as thick as the new cartilage on the epiphyseal end of the plate. Thus, bone growth is made possible by the growth and death of cartilage, which acts to push the epiphysis farther out while it provides a framework for future bone formation on the end of the diaphysis.

MATURE, NONGROWING BONE

As the extracellular matrix produced by an osteoblast calcifies, the osteoblast—like its chondrocyte predecessor—becomes entombed by the matrix it has deposited around itself. Unlike chondrocytes, however, osteoblasts trapped within a calcified matrix do not die, because they are supplied by nutrients transported to them through small canals that the osteoblasts themselves form by sending out cytoplasmic extensions around which the bony matrix is deposited. Thus, within the final bony product a network of permeating tunnels radiates from each entrapped osteoblast, serving as a lifeline system for nutrient delivery and waste removal. The entrapped osteoblasts, now called **osteocytes**, retire from active bone-forming duty, because their imprisonment prevents them from laying down

FIGURE 5-15 Anatomy and growth of long bones. (a) Anatomy of long bones. (b) Two sections of the same epiphyseal plate at different times, depicting the lengthening of long bones

new bone. However, they are involved in the hormonally regulated exchange of calcium between bone and the blood. This exchange is under the control of parathyroid hormone (discussed in Chapter 6), not GH.

GROWTH-PROMOTING ACTIONS OF GH ON BONES

GH promotes growth of bone in both thickness and length. It stimulates osteoblast activity and the proliferation of epiphyseal cartilage, thereby making space for more bone formation. GH can promote lengthening of long bones as long as the epiphyseal plate remains cartilaginous, or is “open.” At the end of adolescence, under the influence of the sex hormones these

plates completely ossify, or “close,” so that the bones cannot lengthen any further despite the presence of GH. Thus, after the plates are closed, the individual does not grow any taller.

Clinical Connections

Michael was much shorter than other children his age because his anterior pituitary was releasing very little growth hormone, which severely decreased the rate of long-bone elongation. Treatment with hGH will allow his bones to continue to elongate but he will remain shorter than his peers.

Somatomedins

According to the traditional view of endocrinologists, GH does not act directly on its target cells to bring about its growth-producing actions (increased cell division, enhanced protein synthesis, and bone growth). When GH is supplied directly to chondrocytes outside the body (i.e., cultured), there appears to be no effect (e.g., enlargement). But when GH is provided *in vivo*, the same chondrocytes begin to proliferate and enlarge. This shows that the effects of GH are indirectly brought about by peptide mediators known as **somatomedins**. These peptides are also referred to as **insulin-like growth factors (IGF)** because they are structurally and functionally similar to insulin. Two somatomedins—IGF-I (IGF-1) and IGF-II (IGF-2)—have been identified. However, by far the most important somatomedin is IGF-I. Recent studies suggest that in addition to working together, GH and IGF-I each act independently to promote growth.

IGF-I

IGF-I synthesis is stimulated by GH and mediates much of this hormone's growth-promoting actions. The concentration of IGF-I in the blood plasma normally mimics the rate of secretion of GH. However, GH's duration of action is short, because GH attaches weakly to the plasma proteins in the blood and it is quickly released into the tissues. Its half-life in the blood is about 20 minutes. In contrast, IGF-I's half-life is approximately 20 hours, because it tightly binds the blood plasma proteins. This association with IGF-I allows the effects of GH to be more prolonged. The major source of circulating IGF-I is the liver, which releases this peptide product into the blood in response to GH stimulation. IGF is also produced by most other tissues, although they do not release it into the blood to any extent. Researchers propose that IGF-I produced locally in target tissues may act through paracrine means (p. 51). For example, the injection of GH into epiphyseal cartilage of bone causes growth within that specific cartilage, which indicates that the localized release of IGF-I by the tissue has a significant effect. Such a mechanism could explain why blood levels of GH are no higher, and indeed circulating IGF-I levels are lower, during the first several years of life compared with adult values, even though growth is quite rapid during the postnatal period. Local production of IGF-I in target tissues may possibly be more important than delivery of blood-borne IGF-I or GH during this time.

Production of IGF is controlled by a number of factors other than GH, including nutritional status, age, and tissue-specific factors, as follows:

- IGF-I production depends on adequate nutrition. Inadequate food intake reduces IGF-I production. As a result, changes in circulating IGF-I levels do not always coincide with changes in GH secretion. For example, fasting decreases IGF-I levels even though it increases GH secretion.
- Age-related factors influence IGF-I production. A dramatic increase in circulating IGF-I levels accompanies the moderate increase in GH at puberty, which may, of course, be an impetus to the pubertal growth spurt.

- Finally, various tissue-specific stimulatory factors can increase IGF-I production in particular tissues. To illustrate, the gonadotropins and sex hormones stimulate IGF-I production within reproductive organs, such as the testes in males and the ovaries and uterus in females.

Thus, control of IGF-I production is complex and subject to a variety of systemic and local factors. (For further discussion of the interaction and influence of GH and IGF-I, see Concepts, Challenges, and Controversies, p. 236.)

IGF-II

In contrast to IGF-I, the production of IGF-II is not influenced by GH. **IGF-II** is primarily important during fetal development. Although IGF-II continues to be produced during adulthood, its role in adults remains unclear.

The following are the basic physiological actions of GH—accomplished either directly or through somatomedins (IGFs):

- Decreased glycogen synthesis
- Reduced glucose use
- Increased lipolysis (breakdown of stored fat)
- Increased use of fatty acids
- Metabolic sparing of glucose and amino acids
- Increased amino acid transport across cell membrane
- Increased protein synthesis
- Increased collagen synthesis
- Increased cartilage growth
- Promotion of hypertrophy and hyperplasia of tissues

Secretion

The control of GH secretion is complex, with two hypothalamic hypophysiotropic hormones playing a key role.

GROWTH HORMONE-RELEASING HORMONE AND GROWTH HORMONE-INHIBITING HORMONE

Two antagonistic regulatory hormones from the hypothalamus are involved in controlling growth hormone secretion: growth hormone-releasing hormone (GHRH), which is stimulatory, and growth hormone-inhibiting hormone (GHIH or somatostatin), which is inhibitory (▶ Figure 5-16). (Note the distinctions among *somatotropin*, alias growth hormone; *somatomedin*, a liver hormone that directly mediates the effects of GH; and *somatostatin*, which inhibits GH secretion.) Any factor that increases GH secretion could theoretically do so either by stimulating GHRH release or by inhibiting GHIH release. Endocrinologists do not know which of these pathways is used in each specific case.

As with the other hypothalamus–anterior pituitary axes, negative-feedback loops participate in the regulation of GH secretion. Both GH and the somatomedins inhibit pituitary secretion of GH, presumably by stimulating GHIH release from the hypothalamus. The somatomedins may also directly influence the anterior pituitary to inhibit the effects of GHRH on GH release.

GROWTH HORMONE (GH) IS A HORMONE that stimulates growth and cell reproduction in humans and other animals. It is a single-chain polypeptide (191-amino acid) hormone that is synthesized, stored, and secreted by the anterior pituitary gland (somatotroph cells). Growth hormone is now synthetically produced via recombinant DNA (rhGH) technology.

GH is used for the treatment of several diseases (e.g., GH-replacement therapy in adults). The genes for human growth hormone are located on chromosome 17 and are closely related to human chorionic somatomammotropin genes. GH, human chorionic somatomammotropin, and prolactin (PRL) are a group of homologous hormones with growth-promoting and lactogenic activity. The two major regulators of GH are peptides: growth hormone–releasing hormone, which is stimulating; and somatostatin, which is inhibiting. Released into the portal vein by the hypothalamus, these peptides bathe the anterior pituitary gland. However, many physiological factors influence these stimulating and inhibiting peptides, including the following:

- Growth hormone–releasing hormone (arcuate nucleus)
- Ghrelin (peptide hormone secreted by the stomach)
- Sleep
- Exercise
- Low levels of blood sugar (hypoglycaemia)
- Dietary protein
- Estradiol
- Arginine

Inhibitors of GH secretion include the following:

- Somatostatin (peptide produced by the periventricular nucleus and other tissues)
- GH and IGF-I concentrations
- Hyperglycaemia
- Glucocorticoids

FACTORS THAT INFLUENCE GH SECRETION

A number of factors influence GH secretion by acting on the hypothalamus. GH secretion displays a well-characterized diurnal rhythm. Through most of the day, GH levels tend to be low and fairly constant. About an hour after the onset of deep sleep, however, GH secretion markedly increases, up to five times the daytime value, and then rapidly drops over the next several hours.

Superimposed on this diurnal fluctuation in GH secretion are further bursts in secretion that occur in response to exercise, stress, and low blood glucose, the major stimuli for increased secretion. The benefits of increased GH secretion during these situations when energy demands outstrip the body's glucose reserves are presumably that glucose is conserved for the brain and fatty acids are provided as an alternative energy source for muscle.

The secretion of GH occurs each day in several large pulsatile peaks, with a typical duration lasting from 10 to 30 minutes, and changes in the plasma concentration of GH ranging from approximately 5 to >35 ng/mL (between peaks basal GH level is usually >3 ng/mL over a 24-hour period). There is wide disparity in GH peaks between days and among individuals, but the most predictable of these peaks occurs about an hour after the onset of sleep. Additionally, the amplitude and pattern of GH secretion change throughout the lifetime. Basal levels are greatest during childhood, the amplitude and frequency of peaks are largest during puberty, and basal levels and the amplitude and frequency of peaks decline throughout adulthood.

The Effects of Growth Hormone

The effects of growth hormone on human tissues are anabolic in nature. Growth hormone acts by interacting with a specific receptor on the surface of cells. For example, GH acts directly on adipocytes, stimulating the breakdown of triglycerides, while suppressing the ability to uptake and accumulate circulating lipids. One of the primary roles of GH is to stimulate the liver and other tissues (e.g., skeletal muscle) to secrete insulin-like growth factor-I (IGF-I). IGF-I stimulates proliferation of chondrocytes (cartilage cells), resulting in bone growth as well as skeletal muscle growth. The influence of GH on skeletal muscle development is via its inhibitory influence on myostatin.

Myostatin is a cytokine that inhibits myogenesis (formation of muscle tissue); thus, the cytokine myostatin is catabolic in nature. GH has an inhibitory effect on myostatin mRNA expression. It is suspected (by in vitro studies) that skeletal muscle cells may demonstrate a significant reduction in myostatin expression by myotubes in response to GH. The result (by in vivo studies) is an increase in lean body mass (e.g., skeletal muscle tissue), which translates into improved athletic performance (e.g., aerobic performance, strength, and power). As long

Because GH uses up fat stores and promotes synthesis of body proteins, it encourages a change in body composition away from adipose deposition toward an increase in muscle protein. Accordingly, the increase in GH secretion that accompanies exercise may at least in part mediate the effects of exercise in reducing the percentage of body fat while increasing the lean body mass.

A rise in blood amino acids after a high-protein meal also enhances GH secretion. In turn, GH promotes the use of these amino acids for protein synthesis. GH is also stimulated by a decline in blood fatty acids. Because GH mobilizes fat, such regulation helps maintain fairly constant blood fatty acid levels.

Note that the known regulatory inputs for GH secretion are aimed at adjusting the levels of glucose, amino acids, and fatty acids in the blood. No known growth-related signals influence

as GH levels are elevated, the inhibitory influence on myostatin can be sustained, maintaining lean body mass. GH assists in the following:

- Strengthens and increases the mineralization of bone
- Increases skeletal muscle mass
- Promotes lipolysis (fat breakdown)
- Increases protein synthesis
- Stimulates the growth of internal organs
- Reduces liver uptake of glucose
- Promotes gluconeogenesis in the liver
- Contributes to the maintenance and function of pancreatic islets
- Stimulates the immune system

Use of Growth Hormone

Because of GH's influence on bone and skeletal muscle, it has been studied as a potential anti-aging treatment since the 1990s. Some research has demonstrated that GH supplementation in elderly men and women can significantly increase lean body mass, bone mineral density, and upper and lower body strength, as well as decrease fat mass. However, other research has found no improvement in bone density, cholesterol levels, maximal oxygen consumption, or muscle strength.

As well, habitual use of GH has demonstrated several negative side effects, such as joint swelling, joint pain, and an increased risk of diabetes. It is because of the potential positive side effects that athletes have become interested in the potential benefits of using rhGH as an ergogenic aid. The scientific evidence to validate the effectiveness of rhGH in athletic populations is lacking as a result of prudent scientific ethical guidelines. The doses of rhGH (anecdotally) used by athletes would generally exceed what is considered acceptable and safe by Research Ethics Boards in Canada and the United States, making verification of the ergogenic benefits in athletic populations difficult.

GH secretion. The whole issue of what really controls growth is complicated by the fact that GH levels during early childhood—a period of quite rapid linear growth—are similar to those in normal adults. As mentioned earlier, the poorly understood control of IGF-I activity may be important in this regard. Another related question is, Why aren't adult tissues still responsive to GH's growth-promoting effects? We know we do not grow any taller after adolescence because the epiphyseal plates have closed, but why don't soft tissues continue to grow through hypertrophy and hyperplasia under the influence of GH? One speculation is that levels of GH may be high enough to produce its growth-promoting effects only during the secretion bursts that occur in deep sleep. It is interesting to note that time spent in deep sleep is greatest in infancy and gradually declines with age. Still, even as we age, we spend some time in deep sleep, yet we do not

The scientific community must base its educated opinion on research involving more therapeutic doses, which is more speculative in nature. A critical review of the current literature pertinent to rhGH's effectiveness in benefiting athletic performance by increasing muscular size and strength was undertaken by Dr. Dean at the University of Manitoba. His literature review (2002) suggested that administration of rhGH in athletes did not significantly improve muscular strength and thus athletic performance. However, more research is needed in this area to better determine the influence of rhGH on athletic performance, but as previously mentioned this will be a challenging task.

Regulation of rhGH in Athletic Competition

The use of rhGH by athletes for ergogenic purposes is banned by the World Anti-Doping Agency (WADA). WADA's position on rhGH is clear and can be found on its website (<http://www.wada-ama.org>). WADA outlines the properties of HGH (same as rhGH), the side effects, the existence of a test, the reliability of testing, and other factors pertinent to informing the athlete of their responsibility and WADA's position. Despite the unproven benefits of rhGH on athletic performance, and its ban by WADA, some athletes continue to use it.

gradually get larger. Further research is needed to unravel these mysteries.

Clinical Connections

Recall that Michael was found to have normal levels of growth hormone-releasing hormone yet low levels of both growth hormone and insulin-like growth factor (IGF-1). Further tests did not show any kind of tumour or lesion within the anterior pituitary. When treated with human growth hormone (hGH), his IGH-1 levels also increased. Taken together, it can be concluded that the cause of Michael's dwarfism is that the anterior pituitary gland does not release growth hormone. Review ▶ Figure 5-16 to understand the role of IGF-1 in the diagnosis.

© 2016 Cengage

*These factors all increase growth hormone secretion, but it is unclear whether they do so by stimulating GHRH or inhibiting somatostatin (GHIH), or both.

► FIGURE 5-16 Control of growth hormone secretion

Aberrant growth patterns

Diseases related to both deficiencies and excesses of growth hormone can occur. The effects on the pattern of growth are much more pronounced than the metabolic consequences.

GROWTH HORMONE DEFICIENCY

GH deficiency may be caused by a pituitary defect (lack of GH) or may occur secondary to hypothalamic dysfunctions (lack of GHRH). Hyposecretion of GH in a child is one cause of

dwarfism. The predominant feature is short stature caused by retarded skeletal growth (► Figure 5-17). Less obvious characteristics include poorly developed muscles (reduced muscle protein synthesis) and excess subcutaneous fat (less fat mobilization).

In addition, growth may be thwarted because the tissues fail to respond normally to GH. An example is **Laron dwarfism**, which is characterized by abnormal GH receptors that are unresponsive to the hormone. The symptoms of this condition resemble those of severe GH deficiency even though blood levels of GH are actually high.

In some instances, GH levels are adequate and target-cell responsiveness is normal, but somatomedins are lacking. African Pygmies are an interesting example; their short stature is attributable to a congenital incapacity to produce a normal amount of IGF-I.

The onset of GH deficiency in adulthood after growth is already complete produces relatively few symptoms. GH-deficient adults tend to have reduced skeletal muscle mass and strength (less muscle protein) as well as decreased bone density (less osteoblast activity during ongoing bone remodeling). Furthermore, because GH is essential for maintaining cardiac muscle mass and performance in adulthood, GH-deficient adults may be at increased risk of developing heart failure.

GROWTH HORMONE EXCESS

Hypersecretion of GH is most often caused by a tumour of the GH-producing cells of the anterior pituitary. The symptoms depend on the age of the individual when the abnormal secretion begins. If overproduction of GH begins in childhood before the epiphyseal plates close, the principal manifestation is a rapid growth in height without distortion of body proportions. Appropriately, this condition is known as **gigantism** (see ► Figure 5-17). If not treated by removal of the

tumour or by drugs that block the effect of GH, the person may reach a height of 2.4 metres or more. All the soft tissues grow correspondingly, so the body is still well proportioned.

If GH hypersecretion occurs after adolescence when the epiphyseal plates have already closed, further growth in height is prevented. Under the influence of excess GH, however, the bones become thicker, and the soft tissues, especially connective tissue and skin, proliferate. This disproportionate growth pattern produces a disfiguring condition known as **acromegaly** (*acro* means “extremity”; *megaly* means “large”). Bone thickening is

SPL/Science Source

► **FIGURE 5-17** Examples of the effect of abnormalities in growth hormone secretion on growth. The man on the left displays pituitary dwarfism resulting from underproduction of growth hormone in childhood. The man at the centre of the photograph has gigantism caused by excessive growth hormone secretion in childhood. The woman at the right is of average height.

most obvious in the extremities and face. The gradual thickening of the facial bones and the skin result in the jaws and cheekbones becoming more prominent (► Figure 5-18). The hands and

feet enlarge, and the fingers and toes become greatly thickened. Peripheral nerve disorders often occur as nerves are entrapped by overgrown connective tissue or bone.

Other hormones

Several other hormones in addition to GH contribute in special ways to overall growth.

- *Thyroid hormone* is essential for growth but is not itself directly responsible for promoting growth. It plays a permissive role in skeletal growth; specifically, the actions of GH fully manifest only when enough thyroid hormone is present. As a result, growth is severely stunted in hypothyroid children, and hypersecretion of thyroid hormone may result in excessive skeletal growth, which increases the child's height.
- *Insulin* is an important growth promoter. Insulin deficiency often blocks growth, and hyperinsulinism frequently spurs excessive growth. Because insulin promotes protein synthesis, its growth-promoting effects should not be surprising. However, these effects may also arise from a mechanism other than insulin's direct effect on protein synthesis. Insulin structurally resembles the somatomedins and may interact with the somatomedin (IGF-I) receptor, which is very similar to the insulin receptor.
- *Androgens*, which are believed to play an important role in the pubertal growth spurt, powerfully stimulate protein synthesis in many organs. Androgens stimulate linear growth, promote weight gain, and increase muscle mass. The most potent androgen, testicular testosterone, is responsible for the general development of heavier musculature in men than in women. These androgenic growth-promoting effects depend on the presence of GH. Androgens have virtually no effect on body growth in the absence of GH, but in its presence they

5

► **FIGURE 5-18** Progressive development of acromegaly. In this series of photos from childhood to early adulthood, note that the brow bones, cheekbones, and jawbones become more prominent. This results from progressive thickening of the bones and skin due to excessive GH secretion.

synergistically enhance linear growth. Although androgens stimulate growth, they ultimately stop further growth by promoting closure of the epiphyseal plates.

- *Estrogens*, like androgens, ultimately terminate linear growth by stimulating complete conversion of the epiphyseal plates to bone. However, the effects of estrogen on growth prior to bone maturation are not well understood. Some studies suggest that large doses of estrogen may even hinder further body growth by inhibiting chondrocyte proliferation while the epiphyseal plates are still open.

Several factors contribute to the average height differences between men and women. First, because puberty occurs about two years earlier in girls than in boys, on average boys have two more years of prepubertal growth than girls do. As a result, boys are usually several inches taller than girls at the start of their respective growth spurts. Second, as already mentioned, boys experience a greater androgen-induced growth spurt than girls before their respective gonadal steroids seal their long bones from further growth; this results in greater heights in men than in women, on average. Third, the pubertal rise in estrogen may reduce the pubertal growth spurt in females. Fourth, recent evidence suggests that androgens “imprint” the brains of males during development, giving rise to a secretory pattern of GH typical in males, characterized by higher cyclic peaks, which are speculated to contribute to the greater height of males.

In addition to these hormones that exert overall effects on body growth, a number of poorly understood peptide *growth factors* have been identified that stimulate mitotic activity of specific tissues (e.g., epidermal growth factor).

We now shift our attention to the other central endocrine gland—the pineal gland.

Check Your Understanding 5.4

1. Describe GH's metabolic effects.
2. Explain the relationship between GH and IGF-I in promoting growth.
3. What factors can influence the release of growth hormone?

5.7 | Pineal Gland and Circadian Rhythms

The **pineal gland**, a tiny, pinecone-shaped structure located in the centre of the brain (see ▶ Figure 5-1), secretes the hormone **melatonin**. (Do not confuse melatonin with the skin-darkening pigment, *melanin*.) Although melatonin was discovered in 1959, investigators have only recently begun to unravel its many functions. One of melatonin's most widely accepted roles is helping to keep the body's inherent circadian rhythms in synchrony with the light–dark cycle. We first examine circadian rhythms in general and then look at the role of melatonin in this regard and in other functions.

The suprachiasmatic nucleus

Hormone secretion rates are not the only factor in the body that fluctuates cyclically over a 24-hour period. Humans have similar biological clocks for many other bodily functions, ranging from gene expression to physiological processes, such as temperature regulation (p. 710), to behaviour. The master biological clock that serves as the pacemaker for the body's circadian rhythms is the **suprachiasmatic nucleus (SCN)**. It consists of a cluster of nerve cell bodies in the hypothalamus above the optic chiasm, the point at which part of the nerve fibres from each eye cross to the opposite half of the brain (*supra* means “above”; *chiasm* means “cross”) (p. 166; see Figure 3-7 and ▶ Figure 5-9). The self-induced rhythmic firing of the SCN neurons plays a major role in establishing many of the body's inherent daily rhythms.

ROLE OF CLOCK PROTEINS

Scientists have now unravelled the underlying molecular mechanisms responsible for the SCN's circadian oscillations. Specific self-starting genes within the nuclei of SCN neurons set in motion a series of events that brings about the synthesis of **clock proteins** in the cytosol surrounding the nucleus. As the day wears on, these clock proteins continue to accumulate, finally reaching a critical mass, at which time they are transported into the nucleus. Here, they block the genetic process responsible for their own production. The level of clock proteins gradually dwindles as they degrade within the nucleus, thus removing their inhibitory influence from the clock-protein genetic machinery. No longer blocked, these genes once again rev up the production of more clock proteins, as the cycle repeats itself. Each cycle takes about a day. The fluctuating levels of clock proteins bring about cyclic changes in neural output from the SCN that, in turn, lead to cyclic changes in effector organs throughout the day. An example is the diurnal variation in cortisol secretion (see ▶ Figure 5-3). Circadian rhythms are therefore linked to fluctuations in clock proteins, which use a feedback loop to control their own production. In this way, internal timekeeping is a self-sustaining mechanism built into the genetic makeup of the SCN neurons.

SYNCHRONIZATION OF THE BIOLOGICAL CLOCK WITH ENVIRONMENTAL CUES

On its own, this biological clock generally cycles a bit slower than the 24-hour environmental cycle. Without any external cues, the SCN sets up cycles that average about 25 hours. The cycles are consistent for a given individual but vary somewhat among different people. If this master clock were not continually adjusted to keep pace with the world outside, the body's circadian rhythms would become progressively out of sync with the cycles of light (periods of activity) and dark (periods of inactivity). As a result, the SCN must be reset daily by external cues so that the body's biological rhythms are synchronized with the activity levels driven by the surrounding environment. The effect of not maintaining the internal clock's relevance to the environment is well known by people who experience **jet lag** when their inherent rhythm is out of step with external cues. The SCN works in conjunction with the pineal gland and its hormonal

RESearch shows that the hectic pace of modern life—the stress, noise, pollution, and the irregular schedules many workers follow—can upset internal rhythms, illustrating how a healthy external environment affects our own internal environment and our health.

Dr. Richard Restak, a neurologist and author, notes that the “usual rhythms of wakefulness and sleep ... seem to exert a stabilizing effect on our physical and psychological health.” The greatest disrupter of our natural circadian rhythms is the variable work schedule, surprisingly common in industrialized countries. Today, one out of every four working men and one out of every six working women has a variable work schedule—that is, shifting frequently between day and night work. In many industries, to make optimal use of equipment and buildings, workers are on the job day and night. As a spin-off, more restaurants and stores stay open 24 hours a day and more health-care workers must be on duty at night to care for accident victims.

To spread the burden, many companies that maintain shifts around the clock alter their workers’ schedules. One week, employees work the day shift. The next week, they move to the “graveyard shift” from midnight to 8 a.m. The next week, they work the night shift from 4 p.m. to midnight. Many shift workers feel tired most of the time and have trouble staying awake at the job. Work performance suffers because of the workers’ fatigue. When workers arrive home for bed, they’re exhausted but can’t sleep, because they’re trying to doze off at a time when the body is trying to wake them up. Unfortunately, the weekly changes in schedule never permit workers’ internal alarm clocks to fully adjust. Most people require 4–14 days to adjust to a new schedule.

Workers on alternating shifts suffer more ulcers, insomnia, irritability, depression, and tension than workers on unchanging shifts. Their lives are never the same. To make matters worse, tired, irritable workers whose judgment is impaired by fatigue pose a threat to society as a whole. Consider an example.

At 4 a.m. in the control room of the Three Mile Island nuclear reactor in Pennsylvania, three operators made the first mistake in a series of errors that led to the worst nuclear accident in U.S. history. The operators did not notice warning lights and failed to observe that a crucial valve had remained open. When the morning-shift operators entered the control room the next day, they quickly discovered the problems, but it was too late. Pipes in the system had burst, sending radioactive steam and water into the air and into two buildings. John Gofman and Arthur Tamplin, two radiation health experts, estimate that the radiation released from the accident will cause at least 300 and possibly as

many as 900 additional fatal cases of cancer in the residents living near the troubled reactor, although other experts (especially in the nuclear industry) contest these projections, saying the accident will have no noticeable effect. Whatever the outcome, the 1979 accident at Three Mile Island cost several billion dollars to clean up.

Late in April 1986, another nuclear power plant ran amok. This accident, in Chernobyl in the former Soviet Union, was far more severe. In the early hours of the morning, two engineers were testing the reactor. Violating standard operational protocol, they deactivated key safety systems. This single error in judgment (possibly caused by fatigue) led to the largest and most costly nuclear accident in world history. Steam built up inside the reactor and blew the roof off the containment building. A thick cloud of radiation rose skyward and then spread throughout Europe and the world. While workers battled to cover the molten radioactive core that spewed radiation into the sky, the whole world watched in horror.

The Chernobyl disaster, like the accident at Three Mile Island, may have been the result of workers operating at a time unsuitable for clear thinking. One has to wonder how many plane crashes, auto accidents, and acts of medical malpractice can be traced to judgment errors resulting from our insistence on working against inherent body rhythms.

Thanks to studies of biological rhythms, researchers are finding ways to reset biological clocks, which could help lessen the misery and suffering of shift workers and could improve the performance of the graveyard-shift workers. For instance, one simple measure is to put shift workers on three-week cycles to give their clocks time to adjust. And instead of shifting workers from daytime to graveyard shifts, transfer them forward, rather than backward (e.g., from a daytime to a nighttime shift). It’s a much easier adjustment. Bright lights can also be used to reset the biological clock. It’s a small price to pay for a healthy workforce and a safer society. Furthermore, use of supplemental melatonin, the hormone that sets the internal clock to march in step with environmental cycles, may prove useful in resetting the body’s clock when that clock is out of synchrony with external cues.

product melatonin to synchronize the various circadian rhythms with the 24-hour day–night cycle. For a discussion of problems associated with being out of sync with environmental cues, see Concepts, Challenges, and Controversies, p. 241.

Melatonin

Daily changes in light intensity are the major environmental cue for the body to adjust the SCN master clock. Special photoreceptors in the retina pick up light signals and transmit them

directly to the SCN. These photoreceptors are distinct from the rods and cones used to perceive, or see, light (p. 161). Scientists recently discovered that **melanopsin**, a protein found in a special retinal ganglion cell (p. 157), is the receptor for light that keeps the body in tune with external time. The vast majority of retinal ganglion cells receive input from the rod and cone photoreceptors. The axons of these ganglion cells form the *optic nerve* that carries information to the visual cortex in the occipital lobe (p. 166). Intermingled among the visually oriented retinal ganglion cells, about 1 to 2 percent of the retinal ganglion cells instead form an entirely independent light-detection system that responds to levels of illumination, like a light meter on a camera, rather than the contrasts, colours, and contours detected by the image-forming visual system. The melanopsin-containing, illumination-detecting retinal ganglion cells cue the pineal gland about the absence or presence of light by sending their signals along the **retino-hypothalamic tract** to the SCN. This pathway is distinct from the neural systems that result in vision perception. The SCN relays the message regarding light status to the pineal gland. This is the major way the internal clock is coordinated to a 24-hour day. Melatonin is the hormone of darkness. Melatonin secretion increases up to tenfold during the darkness of night and then falls to low levels during the light of day. Fluctuations in melatonin secretion, in turn, help entrain the body's biological rhythms with the external light-dark cues.

Proposed roles of melatonin besides regulating the body's biological clock include the following:

- Melatonin induces a natural sleep without the side effects that accompany hypnotic sedatives.
- Melatonin is believed to inhibit the hormones that stimulate reproductive activity. Puberty may be initiated by a reduction in melatonin secretion.

Chapter in Perspective: Focus on Homeostasis

The endocrine system is one of the body's two major regulatory systems; the other is the nervous system. Through its relatively slowly acting hormone messengers, the endocrine system generally regulates activities that require duration rather than speed. Most of these activities are directed toward maintaining homeostasis. The specific contributions of the central endocrine organs to homeostasis are as follows:

- The hypothalamus–posterior pituitary unit secretes vasopressin, which acts on the kidneys during urine formation to help maintain water balance. Control of water balance, in turn, is essential for maintaining ECF osmolarity and proper cell volume.
- For the most part, the hormones secreted by the anterior pituitary do not directly contribute to homeostasis. Instead, most are tropic; that is, they stimulate the secretion of other hormones.
- However, growth hormone from the anterior pituitary, in addition to its growth-promoting actions, also exerts metabolic effects

- In a related role, in some species, seasonal fluctuations in melatonin secretion associated with changes in the number of daylight hours are important triggers for seasonal breeding, migration, and hibernation.
- In another related role, melatonin is being used in clinical trials as a method of birth control, because at high levels it shuts down ovulation (egg release). A male contraceptive using melatonin to stop sperm production is also under development.
- Melatonin appears to be a very effective **antioxidant**, a defence tool against biologically damaging free radicals. *Free radicals* are very unstable electron-deficient particles that are highly reactive and destructive. Free radicals have been implicated in several chronic diseases, such as coronary artery disease (p. 374) and cancer, and are believed to contribute to the aging process.
- Evidence suggests that melatonin may slow the aging process, perhaps by removing free radicals or by other means.
- Melatonin appears to enhance immunity and has been shown to reverse some of the age-related shrinkage of the thymus, the source of T lymphocytes (p. 474), in old experimental animals. Melatonin taken in coordination with calcium is a potent stimulator of the T cell response.

Because of melatonin's many proposed roles, use of supplemental melatonin for a variety of conditions is very promising. However, most researchers are cautious about recommending supplemental melatonin until its effectiveness as a drug is further substantiated. Meanwhile, many people are turning to melatonin as a health food supplement; as such, it is not regulated by Health Canada for safety and effectiveness. The two biggest self-prescribed uses of melatonin are as a prevention for jet lag and as a sleep aid.

that help maintain the plasma concentration of amino acids, glucose, and fatty acids.

- The pineal gland secretes melatonin, which helps entrain the body's circadian rhythm to the environmental cycle of light (period of activity) and dark (period of inactivity).

The peripheral endocrine glands further help maintain homeostasis in the following ways:

- Hormones help maintain the proper concentration of nutrients in the internal environment by directing chemical reactions involved in the cellular uptake, storage, and release of these molecules. Furthermore, the rate at which these nutrients are metabolized is controlled in large part by the endocrine system.
- Salt balance, which is important in maintaining the proper ECF volume and arterial blood pressure, is achieved by hormonally controlled adjustments in salt reabsorption by the kidneys during urine formation.
- Likewise, hormones act on various target cells to maintain the plasma concentration of calcium and other electrolytes. These electrolytes, in turn, play key roles in homeostatic activities.

For example, maintenance of calcium levels within narrow limits is critical for neuromuscular excitability and blood clotting, among other life-supporting actions.

- The endocrine system orchestrates a wide range of adjustments that help the body maintain homeostasis in response to stressful situations.

- The endocrine and nervous systems work in concert to control the circulatory and digestive systems, which in turn carry out important homeostatic activities.

Unrelated to homeostasis, hormones direct the growing process and control most aspects of the reproductive system.

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-40)

1. One endocrine gland may secrete more than one hormone. (*True or false?*)
2. One hormone may influence more than one type of target cell. (*True or false?*)
3. All endocrine glands are exclusively endocrine in function. (*True or false?*)
4. A single target cell may be influenced by more than one hormone. (*True or false?*)
5. Hyposecretion or hypersecretion of a specific hormone can occur even though its endocrine gland is perfectly normal. (*True or false?*)
6. Growth hormone levels in the blood are no higher during the early childhood growing years than during adulthood. (*True or false?*)
7. A hormone that has as its primary function the regulation of another endocrine gland is classified functionally as a _____ hormone.
8. Self-induced reduction in the number of receptors for a specific hormone is known as _____.
9. Activity within the cartilaginous layer of bone known as the _____ is responsible for lengthening of long bones.
10. The _____ in the hypothalamus is the body's master biological clock.
11. Indicate the relationships among the hormones in the hypothalamic/anterior pituitary/adrenal cortex system by using the following answer code to identify which hormone belongs in each blank:

- (a) cortisol
- (b) ACTH
- (c) CRH

(1) _____ from the hypothalamus stimulates the secretion of (2) _____ from the anterior pituitary. (3) _____, in turn, stimulates the secretion of (4) _____ from the adrenal cortex. In negative-feedback fashion, (5) _____ inhibits secretion of (6) _____ and furthermore reduces the sensitivity of the anterior pituitary to (7) _____.

Written Questions

1. List the overall functions of the endocrine system.
2. How is the plasma concentration of a hormone normally regulated?
3. List and briefly state the functions of the posterior pituitary hormones.
4. List and briefly state the functions of the anterior pituitary hormones.
5. Compare the relationship between the hypothalamus and posterior pituitary with the relationship between the hypothalamus and anterior pituitary. Describe the role of the hypothalamic-hypophyseal portal system and the hypothalamic releasing and inhibiting hormones.
6. Describe the actions of growth hormone that are unrelated to growth. What are growth hormone's growth-promoting actions? What is the role of somatomedins (IGF)?
7. Discuss the control of growth hormone secretion.
8. What are the source, functions, and stimulus for secretion of melatonin?

5

POINTS TO PONDER

(Explanations in Appendix E, p. A-40)

1. Would you expect the concentration of hypothalamic releasing and inhibiting hormones in a systemic venous blood sample to be higher, lower, or the same as the concentration of these hormones in a sample of hypothalamic-hypophyseal portal blood?
2. Thinking about the feedback control loop among TRH, TSH, and thyroid hormone, would you expect the concentration of TSH to be normal, above normal, or below normal in a person whose diet is deficient in iodine (an element essential for synthesizing thyroid hormone)?
3. A patient displays symptoms of excess cortisol secretion. What factors could be measured in a blood sample to determine whether the condition is caused by a defect at the hypothalamic/anterior pituitary level or the adrenal cortex level?
4. Why would males with testicular feminization syndrome be unusually tall?
5. A black market for growth hormone abuse already exists among weightlifters and other athletes. What actions of growth hormone would induce a full-grown athlete to take supplemental doses of this hormone? What are the potential detrimental side effects?

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-41)

At 18 years of age and 2.4 metres tall, Anthony O. was diagnosed with gigantism caused by a pituitary tumour. The

condition was treated by surgically removing his pituitary gland. What hormonal replacement therapy would Anthony need?

The Endocrine Glands

Body systems maintain homeostasis

The female endocrine system

Cells make up body systems

Homeostasis

The endocrine system, one of the body's two major regulatory systems, secretes hormones that act on their target cells to regulate the blood concentrations of nutrient molecules, water, salt, and other electrolytes, among other homeostatic activities. Hormones also play a key role in controlling growth and reproduction and in stress adaptation.

Homeostasis is essential for survival of cells

Endocrine gland

The endocrine system, by means of the blood-borne hormones it secretes, generally regulates activities that require duration rather than speed. The peripheral endocrine glands include the thyroid gland, which controls the body's basal metabolic rate; the adrenal glands, which secrete

hormones important in metabolizing nutrient molecules, in adapting to stress, and in maintaining salt balance; the endocrine pancreas, which secretes hormones important in metabolizing nutrient molecules; and the parathyroid glands, which secrete a hormone important in calcium metabolism.

Clinical Connections

Megan, a 19-year-old female, away at university, was studying for mid-term exams when she suddenly experienced a pounding headache, blurred vision, sweating, and a rapid heartbeat. She assumed she was experiencing an anxiety attack due to the upcoming exam so she ignored it and went to bed. In class a few weeks later, she suddenly experienced similar symptoms, but much worse this time. Being away from her family, she decided to go to the hospital emergency room close to campus. Upon presentation, her blood pressure was 170/120 mmHg and her heart rate was 90 bpm, but within the hour her symptoms had vanished, and her blood pressure returned to the higher end of normal. Standard blood work came back normal. She was released and told to follow up with her family physician.

Later that evening she called her parents to tell them what had happened. Her father told her that his brother frequently had symptoms like that for years before he passed away at an age of 35 from what everyone assumed was a heart attack. The next day the symptoms returned, and she went again to the emergency room. Upon hearing her updated family history, the doctor ordered additional tests, including blood work, urine analysis, and an MRI. The urine analysis showed high concentrations of catecholamine metabolites, and an MRI found a tumour in the celiac ganglia. Ultimately she was diagnosed with pheochromocytoma due to an extra-adrenal paraganglioma.

6.1 | Thyroid Gland

The **thyroid gland** consists of two lobes of endocrine tissue joined in the middle by a narrow portion of the gland, giving it a bow-tie shape (► Figure 6-1a). The gland is even located in the appropriate place for a bow tie, lying over the trachea just below the larynx.

Secretion of the thyroid hormone

The major thyroid secretory cells, known as **follicular cells**, are arranged into hollow spheres, each of which forms a functional unit called a **follicle**. On a microscopic section (► Figure 6-1b), the follicles appear as rings of follicular cells enclosing an inner lumen filled with **colloid**—a substance that serves as an extracellular storage site for thyroid hormone. Note that the colloid within the follicular lumen is extracellular (i.e., outside the thyroid cells), even though it is located within the interior of the follicle. Colloid is not in direct contact with the extracellular fluid that surrounds the follicle, similar to an inland lake that is not in direct contact with the oceans that surround a continent.

The chief constituent of the colloid is a large protein molecule known as **thyroglobulin (Tg)**, within which are incorporated the thyroid hormones in their various stages of synthesis. The follicular cells produce two iodine-containing hormones derived from the amino acid tyrosine: **tetraiodothyronine (T_4 or thyroxine)** and **triiodothyronine (T_3)**. The prefixes *tetra* and *tri* and the subscripts 4 and 3 denote the number of iodine atoms incorporated into each of these hormones. Approximately 90 percent of the hormone secreted by the thyroid gland is in the form of T_4 , whereas about 10 percent is in the form of T_3 . These two hormones, collectively referred to as **thyroid hormone**, are important regulators of overall basal metabolic rate. The qualitative function of these hormones is the same, but they differ in their speed and intensity of action.

Interspersed in the interstitial spaces between the follicles is another secretory cell type, the **C cells**, so-called because they secrete the peptide hormone **calcitonin**. Calcitonin plays a role in calcium metabolism and is not related in any way to the two other major thyroid hormones. We discuss calcitonin in Section 6.5, when we examine endocrine control of calcium balance. Here, we discuss T_4 and T_3 .

Synthesis and storage of the thyroid hormone

The basic ingredients for thyroid hormone synthesis are tyrosine and iodine, both of which must be taken up from the blood by the follicular cells. Tyrosine, an amino acid, is synthesized in sufficient amounts by the body, so it is not a dietary essential. By contrast, the iodine needed for thyroid hormone synthesis must be obtained from dietary intake. The dietary iodine intake needed is about 1 mg per week. In the small intestine, dietary iodine is reduced to iodide for transport in the circulation. Most Canadians exceed the daily requirement through the use of common table salt. The synthesis, storage, and secretion of thyroid hormone involve the following process.

(a) Gross anatomy of thyroid gland

(b) Light-microscopic appearance of thyroid gland

► **FIGURE 6-1 Anatomy of the thyroid gland.** (a) Gross anatomy of the thyroid gland, anterior view. The thyroid gland lies over the trachea just below the larynx and consists of two lobes connected by a thin strip called the *isthmus*. (b) Light-microscope appearance of the thyroid gland. The thyroid gland is composed primarily of colloid-filled spheres enclosed by a single layer of follicular cells.

The majority of steps for thyroid hormone synthesis takes place on the thyroglobulin molecules within the colloid. Thyroglobulin itself is produced by the endoplasmic reticulum-Golgi complex of the thyroid follicular cells. Many molecules of the amino acid tyrosine become incorporated in the much larger thyroglobulin molecules as the latter are being produced. Once

produced, tyrosine-containing thyroglobulin is exported from the follicular cells into the colloid by exocytosis (step **1** in > Figure 6-2).

The thyroid captures (traps) iodide from the blood and transfers it into the colloid by an *iodide pump*—the powerful, energy-requiring carrier proteins in the outer membranes of the follicular cells (step **2**). The iodide pump cotransports Na^+ and is driven by the concentration gradient of Na^+ , which is established by the $\text{Na}^+ - \text{K}^+$ pump located on the basolateral

membrane. In moving Na^+ down its concentration gradient, iodide moves *against* its concentration gradient and becomes trapped in the thyroid for thyroid hormone synthesis. The iodide pump concentrates the iodide into the thyroid glandular cells and follicles to about 30 times its concentration in the blood, which is sometimes referred to as *iodide trapping*. Iodide serves no other function in the body.

Once inside the follicular cell, iodide is transported into the colloid of the follicular lumen (step **3**). Within the follicle, iodide

KEY

	= Primary active transport	I^0 = Iodine	MIT = Monoiodotyrosine
	= Secondary active transport (symporter)	Tg = Thyroglobulin	DIT = Di-iodotyrosine
		I^- = Iodide	T_3 = Tri-iodothyronine
		TPO = Thyroperoxidase	T_4 = Tetraiodothyronine (thyroxine)

1 Tyrosine-containing Tg produced within the thyroid follicular cells by the endoplasmic reticulum–Golgi complex is transported by exocytosis into the colloid.

2 Iodide is carried by secondary active transport from the blood into the colloid by symporters in the basolateral membrane of the follicular cells.

3 Iodide exits the cell through a luminal channel to enter the colloid.

4a Catalyzed by TPO, iodide is simultaneously oxidized to iodine (I^0) and attached to tyrosine within the Tg molecule to yield MIT.

4b Attachment of two iodines to tyrosine yields DIT.

5a Coupling of one MIT and one DIT yields T_3 .

5b Coupling of two DITs yields T_4 .

6 On appropriate stimulation, the thyroid follicular cells engulf a portion of Tg-containing colloid by phagocytosis.

7 Lysosomes attack the engulfed vesicle and split the iodinated products from Tg.

8a T_3 and T_4 diffuse into the blood (secretion).

8b MIT and DIT are deiodinated, and the freed iodide is recycled for synthesizing more hormone.

> **FIGURE 6-2** Synthesis, storage, and secretion of thyroid hormone

is rapidly converted into its highly reactive state, iodine, and attached to a tyrosine within the thyroglobulin molecule. This conversion (called *iodide organification*) and attachment occur almost simultaneously and is mediated by the membrane-bound enzyme **thyroperoxidase (TPO)**. Attachment of one iodine to tyrosine yields **monoiodotyrosine (MIT)** (step **4a**). Attachment of two iodines to tyrosine yields **di-iodotyrosine (DIT)** (step **4b**). A coupling process occurs between the iodinated tyrosine molecules to form the thyroid hormones. Coupling of one MIT (with one iodide) and one DIT (with two iodides) yields **triiodothyronine (T_3)** (with three iodides) (step **5a**). Coupling of two DITs (each bearing two iodide atoms) yields **tetraiodothyronine (T_4 or thyroxine)**, the four-iodide form of *thyroid hormone* (step **5b**). *Coupling does not occur between two MIT molecules.*

All these products remain attached to thyroglobulin. Thyroid hormones remain stored in this form in the colloid until they are split off and secreted. The ratio of T_3 to T_4 stored in the colloid is about 1 to 10. Sufficient thyroid hormone is normally stored to supply the body's needs for several months.

Thyroglobulin-laden colloid

The release of thyroid hormone into the systemic circulation is a rather complex process, for two reasons. First, before their release, T_3 and T_4 are still bound within the thyroglobulin molecule. Second, these hormones are stored within the follicular lumen, so they must be transported completely across the follicular cells to reach the capillaries that course through the interstitial spaces between the follicles.

The process of thyroid hormone secretion essentially involves the follicular cells “biting off” a piece of colloid, breaking the thyroglobulin molecule down into its component parts, and “spitting out” the freed T_3 and T_4 into the blood. Upon the appropriate stimulation, thyroglobulin containing colloid is taken into the follicular cells by phagocytosis (step **6**). Once inside the follicular cells, lysosomes fuse with these vesicles and release digestive enzymes that release T_3 and T_4 , as well as the inactive iodotyrosines, MIT and DIT (step **7**).

The thyroid hormones, being very lipophilic, pass freely through the outer membranes of the follicular cells and into the blood (step **8a**). The MIT and DIT are of no endocrine value. The follicular cells contain an enzyme—iodinase—that swiftly removes the iodide from MIT and DIT, allowing the freed iodide to be recycled for synthesis of more hormone (step **8b**). This highly specific enzyme removes iodide only from the worthless MIT and DIT, not from the valuable T_3 or T_4 .

Once released into the blood, the highly lipophilic (and, therefore, water-insoluble) thyroid hormone molecules very quickly bind with several plasma proteins. The majority of circulating T_4 and T_3 is transported by **thyroxine-binding globulin**, a plasma protein that selectively binds only thyroid hormone. The binding affinity is six times as great for T_4 as it is for T_3 . Less than 0.1 percent of the T_4 and less than 1 percent of the T_3 remain in the unbound (free) form. This is remarkable, considering that only the free portion of the total thyroid hormone pool has access to the target-cell receptors and thus can exert an effect.

T_4 and T_3

About 90 percent of the secretory product released from the thyroid gland is in the form of T_4 , yet T_3 is about four times as potent in its biological activity. However, most of the secreted T_4 is converted into T_3 , or *activated*, by being stripped of one of its iodines outside the thyroid gland, primarily in the liver and kidneys. About 80 percent of the circulating T_3 is derived from secreted T_4 that has been peripherally stripped. Therefore, T_3 is the major biologically active form of thyroid hormone at the cellular level, even though the thyroid gland secretes mostly T_4 .

Thyroid hormone and basal metabolic rate

Compared with other hormones, the action of thyroid hormone is sluggish. The response to an increase in thyroid hormone is detectable only after a delay of several hours, and the maximal response is not evident for several days. The duration of the response is also quite long, partially because thyroid hormone is not rapidly degraded but also because the response to an increase in secretion continues to be expressed for days or even weeks after the plasma thyroid hormone concentrations have returned to normal.

Virtually every tissue in the body is affected either directly or indirectly by thyroid hormone. The effects of T_3 and T_4 can be grouped into several overlapping categories.

EFFECT ON METABOLIC RATE AND HEAT PRODUCTION

Thyroid hormone increases the body's overall basal metabolic rate, or “idling speed” (p. 700). It is the most important regulator of the body's rate of O_2 consumption and energy expenditure under resting conditions. The basal metabolic rate can increase to as much as 100 percent above normal when significant amounts of thyroid hormone are released.

Closely related to thyroid hormone's overall metabolic effect is its **calorigenic (heat-producing) effect**. Increased metabolic activity results in increased heat production.

EFFECT ON INTERMEDIARY METABOLISM

In addition to increasing the general metabolic rate, thyroid hormone modulates the rates of many specific reactions involved in fuel metabolism. The effects of thyroid hormone on the metabolic fuels are multifaceted: Not only can it influence both the synthesis and degradation of carbohydrate, fat, and protein, but small or large amounts of the hormone may also induce opposite effects. For example, the conversion of glucose to glycogen (the storage form of glucose) is facilitated by small amounts of thyroid hormone, but the reverse—the breakdown of glycogen into glucose—occurs with large amounts of the hormone. Similarly, adequate amounts of thyroid hormone are essential for the protein synthesis needed for normal bodily growth, yet at high doses, as in thyroid hypersecretion, thyroid hormone favours protein degradation. Because thyroid hormone increases the quantity of enzymes involved in metabolism, there is also an increased need for vitamins, as vitamins are an essential element of some enzymes.

SYMPATHOMIMETIC EFFECT

Any action similar to one produced by the sympathetic nervous system is known as a **sympathomimetic (sympathetic-mimicking) effect**. Thyroid hormone increases target-cell responsiveness to catecholamines (epinephrine and norepinephrine)—the chemical messengers used by the sympathetic nervous system and its hormonal reinforcements from the adrenal medulla. Thyroid hormone accomplishes this permissive action by causing a proliferation of specific catecholamine target-cell receptors (p. 214). Because of this action, many of the effects observed when thyroid hormone secretion is elevated are similar to those that accompany activation of the sympathetic nervous system.

EFFECT ON THE CARDIOVASCULAR SYSTEM

Through its effect of increasing the heart's responsiveness to circulating catecholamines, thyroid hormone increases heart rate and force of contraction, thus increasing cardiac output (p. 365). In addition, in response to the heat load generated by the calorigenic effect of thyroid hormone, peripheral vasodilation occurs to carry the extra heat to the body surface for elimination to the environment (p. 715).

Aside from increasing the excitability and contractility of the heart, thyroid hormone also influences other aspects of the cardiovascular system. For example, thyroid hormone will cause an increase in blood volume and flow, but no change in arterial blood pressure.

EFFECT ON GROWTH AND THE NERVOUS SYSTEM

Thyroid hormone is essential for normal growth because of its effects on growth hormone (GH) and IGF-I (p. 235). Thyroid hormone not only stimulates GH secretion and increases production of IGF-I by the liver but also promotes the effects of GH and IGF-I on the synthesis of new structural proteins and on skeletal growth. Thyroid-deficient children have stunted growth that can be reversed by thyroid replacement therapy. Unlike excess GH, however, excess thyroid hormone does not produce excessive growth.

Thyroid hormone plays a crucial role in the normal development of the nervous system, especially the CNS, an effect impeded in children who have thyroid deficiency from birth. Thyroid hormone is also essential for normal CNS activity in adults.

EFFECT ON SKELETAL MUSCLE

Thyroid hormone—specifically T_3 —has a profound influence on skeletal muscle. T_3 influences gene expression at transcription, posttranscription, translation, and posttranslation. Some examples of T_3 effects on skeletal muscle are increased muscle size, since T_3 influences the distribution of fibre types in the muscle (slow twitch is more sensitive to T_3 than fast twitch); increased calcium uptake by the sarcoplasmic reticulum; and increased maximum shortening velocity of muscle. You will learn about skeletal muscle in Chapter 7.

The hypothalamus–pituitary–thyroid axis

Thyroid-stimulating hormone (TSH), the thyroid tropic hormone from the anterior pituitary, is the most important physiological regulator of thyroid hormone secretion (► Figure 6-3; see

► FIGURE 6-3 Regulation of thyroid hormone secretion

also Chapter 5, p. 227). Almost every step of thyroid hormone synthesis and release is stimulated by TSH.

In addition to enhancing thyroid hormone secretion, TSH maintains the structural integrity of the thyroid gland. In the absence of TSH, the thyroid atrophies (decreases in size) and secretes its hormones at a very low rate. Conversely, it undergoes hypertrophy (increase in the size of each follicular cell) and hyperplasia (increase in the number of follicular cells) in response to excess TSH stimulation.

The hypothalamic thyrotropin-releasing hormone (TRH), in tropic fashion, turns on TSH secretion by the anterior pituitary (p. 229), whereas thyroid hormone, in negative-feedback fashion, turns off TSH secretion by inhibiting the anterior pituitary. Like other negative-feedback loops, the one between thyroid hormone and TSH tends to maintain a stable thyroid hormone output.

Negative feedback between the thyroid and anterior pituitary accomplishes day-to-day regulation of free thyroid hormone levels, whereas the hypothalamus mediates long-term adjustments. Unlike most other hormonal systems, the hormones in the thyroid axis in an adult normally do not undergo sudden, wide swings in secretion. The relatively steady rate of thyroid

hormone secretion is in keeping with the sluggish, long-lasting responses that this hormone induces; there would be no adaptive value in suddenly increasing or decreasing plasma thyroid hormone levels.

The only known factor that increases TRH secretion (and, accordingly, TSH and thyroid hormone secretion) is exposure to cold in newborn infants, a highly adaptive mechanism. Scientists think the dramatic increase in heat-producing thyroid hormone secretion helps maintain body temperature during the abrupt drop in surrounding temperature at birth as the infant passes from the mother's warm body to the cooler environmental air. A similar TSH response to cold exposure does not occur in adults, although it would make sense physiologically and does occur in many types of experimental animals.

Various types of stress inhibit TSH and thyroid hormone secretion, presumably through neural influences on the hypothalamus, although the adaptive importance of this inhibition is unclear.

Abnormalities of thyroid function

Abnormalities of thyroid function are among the most common of all endocrine disorders. They fall into two major categories—**hypothyroidism** and **hyperthyroidism**—reflecting deficient and excess thyroid hormone secretion, respectively. A number of specific causes can give rise to each of these conditions (Table 6-1). Whatever the cause, the consequences of too little or too much thyroid hormone secretion are largely predictable, given knowledge of the functions of thyroid hormone.

HYPOTHYROIDISM

Hypothyroidism can result (1) from primary failure of the thyroid gland itself; (2) secondary to a deficiency of TRH, TSH, or both; or (3) from an inadequate dietary supply of iodine.

The symptoms of hypothyroidism are largely caused by a reduction in overall metabolic activity. Among other things, a

patient with hypothyroidism has a reduced basal metabolic rate; displays poor tolerance of cold (lack of the calorogenic effect); has a tendency to gain excessive weight (not burning fuels at a normal rate); is easily fatigued (lower energy production); has a slow, weak pulse (caused by a reduction in the rate and strength of cardiac contraction and a lowered cardiac output); and exhibits slow reflexes and slow mental responsiveness (because of the effect on the nervous system). The mental effects are characterized by diminished alertness, slow speech, and poor memory.

Another notable characteristic is an oedematous condition caused by infiltration of the skin with complex, water-retaining carbohydrate molecules, presumably as a result of altered metabolism. The resultant puffy appearance, primarily of the face, hands, and feet, is known as **myxoedema**. In fact, the term *myxoedema* is often used as a synonym for hypothyroidism in an adult, because of the prominence of this symptom.

If a person has hypothyroidism from birth, a condition known as **cretinism** develops. Because adequate levels of thyroid hormone are essential for normal growth and CNS development, cretinism is characterized by dwarfism and mental retardation, as well as other general symptoms of thyroid deficiency. The mental retardation is preventable if replacement therapy is started promptly, but it is not reversible once it has developed for a few months after birth, even with later treatment with thyroid hormone.

Treatment of hypothyroidism, with one exception, consists of replacement therapy by administering exogenous thyroid hormone. The exception is hypothyroidism caused by iodine deficiency, in which the remedy is adequate dietary iodine.

HYPERTHYROIDISM

The most common cause of hyperthyroidism is **Graves' disease**. This is an autoimmune disease in which the body erroneously produces **long-acting thyroid stimulator (LATS)**, an antibody whose target is the TSH receptors on the thyroid cells. LATS stimulates both secretion and growth of the thyroid in a manner

TABLE 6-1 Types of Thyroid Dysfunctions

Thyroid Dysfunction	Cause	Plasma Concentrations of Relevant Hormones	Goitre Present?
Hypothyroidism	Primary failure of the thyroid gland	↓ T ₃ and T ₄ , ↑ TSH	Yes
	Secondary to hypothalamic or anterior pituitary failure	↓ T ₃ and T ₄ , ↓ TRH and/or ↓ TSH	No
	Lack of dietary iodine	↓ T ₃ and T ₄ , ↑ TSH	Yes
Hyperthyroidism	Abnormal presence of long-acting thyroid stimulator (LATS) (Graves' disease)	↓ T ₃ and T ₄ , ↓ TSH	Yes
	Secondary to excess hypothalamic or anterior pituitary secretion	↓ T ₃ and T ₄ , ↑ TRH and/or ↑ TSH	Yes
	Hypersecreting thyroid tumour	↓ T ₃ and T ₄ , ↓ TSH	No

► **FIGURE 6-4** Role of long-acting thyroid stimulator in Graves' disease.

Long-acting thyroid stimulator (LATS), an antibody erroneously produced in the autoimmune condition of Graves' disease, binds with the TSH receptors on the thyroid gland and continuously stimulates thyroid hormone secretion outside the normal negative-feedback control system.

similar to TSH. Unlike TSH, however, LATS is not subject to negative-feedback inhibition by thyroid hormone, so thyroid secretion and growth continue unchecked (► Figure 6-4). People with hyperthyroidism have shown secretion rates as great as 10 to 15 times the normal rate. Less frequently, hyperthyroidism occurs secondary to excess TRH or TSH or in association with a hypersecreting thyroid tumour.

As expected, the hyperthyroid patient has an elevated basal metabolic rate. The resultant increase in heat production leads to excessive perspiration and poor tolerance of heat. Despite the increased appetite and food intake that occur in response to the increased metabolic demands, body weight typically falls because the body is burning fuel at an abnormally rapid rate. Net degradation of carbohydrate, fat, and protein stores occurs. The resultant loss of skeletal muscle protein results in weakness. Various cardiovascular abnormalities are associated with hyperthyroidism, caused both by the direct effects of thyroid hormone and by its interactions with catecholamines. Heart rate and strength of contraction may increase so much that the individual has palpitations (an unpleasant awareness of the heart's activity). In severe cases, the heart may fail to meet the body's metabolic demands despite increased cardiac output. The effects on the CNS are characterized by an excessive degree of mental alertness to the point where the patient is irritable, tense, anxious, and excessively emotional.

A prominent feature of Graves' disease but not of the other types of hyperthyroidism is **exophthalmos** (bulging eyes) (► Figure 6-5). Complex, water-retaining carbohydrates are deposited behind the eyes, although why this happens is still unclear. The resulting fluid retention pushes the eyeballs forward so they bulge from their bony orbit. The eyeballs may bulge so far that the lids cannot completely close, in which case the eyes become dry, irritated, and prone to corneal ulceration. Even after correction of the hyperthyroid condition, these troublesome eye symptoms may persist.

► **FIGURE 6-5** A woman with Graves' disease displaying exophthalmos.

Abnormal swelling of muscle and fat behind the eyeballs causes them to bulge forward.

Three general methods of treatment can suppress excess thyroid hormone secretion: surgical removal of a portion of the oversecreting thyroid gland; administration of radioactive iodine, which, after being concentrated in the thyroid gland by the iodide pump, selectively destroys thyroid glandular tissue; and use of antithyroid drugs that specifically interfere with thyroid hormone synthesis.

Thyroid gland overstimulation

Clinical Note A **goitre** is an enlarged thyroid gland. Because the thyroid lies over the trachea, a goitre is readily palpable and usually highly visible (► Figure 6-6). A goitre occurs whenever either TSH or LATS excessively stimulates the thyroid gland. Note from Table 6-1 that a goitre may accompany hypothyroidism or hyperthyroidism, but it need not be present in either condition. Knowing the hypothalamus–pituitary–thyroid axis and feedback control, we can predict which types of thyroid dysfunction will produce a goitre. Let's consider hypothyroidism first.

- Hypothyroidism secondary to hypothalamic or anterior pituitary failure will not be accompanied by a goitre, because the thyroid gland is not being adequately stimulated, let alone excessively stimulated.
- With hypothyroidism caused by thyroid gland failure or lack of iodine, a goitre does develop, because the circulating level of thyroid hormone is so low that there is little negative-feedback inhibition on the anterior pituitary, and TSH secretion is therefore elevated. TSH acts on the thyroid to increase the size and number of follicular cells and to increase their rate of secretion. If the thyroid cells cannot secrete hormone because of a lack of a critical enzyme or lack of iodine, no amount of TSH will be able to induce these cells to secrete T_3 and T_4 . However, TSH can still promote hypertrophy and hyperplasia of the thyroid, with a consequent paradoxical enlargement of the gland (i.e., a goitre), even though the gland is still underproducing.

© Lester V. Bergman/CORBIS

► **FIGURE 6-6** Patient with a goitre

Similarly, a goitre may or may not accompany hyperthyroidism:

- Excessive TSH secretion resulting from a hypothalamic or anterior pituitary defect would obviously be accompanied by a goitre and excess T_3 and T_4 secretion because of overstimulation of thyroid growth. Because the thyroid gland in this circumstance is also capable of responding to excess TSH with increased hormone secretion, hyperthyroidism is present with this goitre.
- In Graves' disease, a hypersecreting goitre occurs because LATS promotes growth of the thyroid, as well as enhancing secretion of thyroid hormone. Because the high levels of circulating T_3 and T_4 inhibit the anterior pituitary, TSH secretion itself is low. In all other cases when a goitre is present, TSH levels are elevated and are directly responsible for excessive growth of the thyroid.
- Hyperthyroidism resulting from overactivity of the thyroid in the absence of overstimulation, such as that caused by an uncontrolled thyroid tumour, is not accompanied by a goitre. The spontaneous secretion of excessive amounts of T_3 and T_4 inhibits TSH, so there is no stimulatory input to promote growth of the thyroid.

Parathyroid glands

There are four parathyroid glands, each the size of rice grain, located on the back surface of the thyroid gland, one in each corner. These glands share the same blood supply and venous drainage as the thyroid gland. Despite their small size, the parathyroid glands are essential for life, meaning that if the glands are removed death with follow, usually within a few days. The primary hormone secreted by the parathyroid gland is named

parathyroid hormone (PTH). The primary role of PTH is to maintain the body's calcium and phosphate levels within a narrow physiological range. Deviation from this range leads to rapid changes in the nervous system and skeletal muscle function, which can be life threatening. We discuss the actions of PTH in detail in Section 6.5, when we examine the endocrine control of calcium metabolism.

Check Your Understanding 6.1

1. Define *thyroid follicle*, *colloid*, *thyroglobulin*, *MIT*, *DIT*, T_3 , and T_4 .
2. Draw a flow diagram showing the effects and regulation of thyroid hormone secretion.
3. Explain how both hyperthyroidism and hypothyroidism can lead to a goitre.

6.2 | Adrenal Glands

There are two **adrenal glands** (4 g each), one embedded above each kidney in a capsule of fat (*ad* means “next to”; *renal* means “kidney”) (► Figure 6-7a).

A steroid-secreting cortex and a catecholamine-secreting medulla

Each adrenal is composed of two endocrine organs, one surrounding the other. The outer layers composing the **adrenal cortex** secrete a variety of steroid hormones; the inner portion, the adrenal medulla, secretes catecholamines. Thus, the adrenal cortex and medulla secrete hormones belonging to different chemical categories, whose functions, mechanisms of action, and regulation are entirely different. We first examine the adrenal cortex and then turn our attention to the adrenal medulla.

Mineralocorticoids, glucocorticoids, and sex hormones

The adrenal cortex consists of three layers or zones: the **zona glomerulosa**, the outermost layer; the **zona fasciculata**, the middle and largest portion; and the **zona reticularis**, the innermost zone (► Figure 6-7b). The adrenal cortex produces a number of different **adrenocortical hormones**, all of which are steroids derived from a common precursor molecule, cholesterol (p. 216). Slight variations in structure confer different functional capabilities on the various adrenocortical hormones (corticosteroids). On the basis of their primary actions, the adrenal steroids can be divided into three categories:

1. **Mineralocorticoids**, mainly *aldosterone*, influence mineral (electrolyte) balance, specifically sodium and potassium balance.
2. **Glucocorticoids**, primarily *cortisol*, play a major role in glucose metabolism as well as in protein and lipid metabolism.

FIGURE 6-7 Anatomy of the adrenal glands. (a) Location and structure of the adrenal glands. (b) Layers of the adrenal cortex

3. **Sex hormones** are identical or similar to those produced by the gonads (testes in males, ovaries in females). The most abundant and physiologically important of the adrenocortical sex hormones is *dehydroepiandrosterone*—considered a male sex hormone, although produced by both men and women.

The three categories of adrenal steroids are produced in anatomically distinct portions of the adrenal cortex. This is due to the differential distribution of the enzymes required to catalyze the different biosynthetic pathways leading to the formation of each of these steroids. Of the two major adrenocortical hormones, aldosterone is produced exclusively in the zona glomerulosa, whereas cortisol synthesis is limited to the two inner layers of the cortex—the zona fasciculata and zona reticularis—with the former being the major source of this glucocorticoid. No other steroidogenic tissues have the capability of producing either mineralocorticoids or glucocorticoids. In contrast, the adrenal sex hormones, also produced by the two inner cortical zones, are produced in far greater abundance in the gonads.

Being lipophilic, the adrenocortical hormones are all carried in the blood extensively bound to plasma proteins. Cortisol is bound mostly to a plasma protein specific for it called

corticosteroid-binding globulin (transcortin), whereas aldosterone and dehydroepiandrosterone are largely bound to albumin, which nonspecifically binds with a variety of lipophilic hormones.

Mineralocorticoids' major effects on Na^+ and K^+ balance

The actions and regulation of the primary adrenocortical mineralocorticoid, **aldosterone**, are described thoroughly in Chapters 13 and 14. The principal site of aldosterone action is on the distal and collecting tubules of the kidney, where it promotes Na^+ retention and enhances K^+ elimination during the formation of urine. The promotion of Na^+ retention by aldosterone secondarily induces osmotic retention of water, expanding the ECF volume, which is important in the long-term regulation of blood pressure.

Mineralocorticoids are *essential for life*. Without aldosterone, a person rapidly dies (in about two days to two weeks) from circulatory shock due to the marked fall in plasma volume caused by excessive losses of H_2O -holding Na^+ . With most other hormonal deficiencies, death is not imminent, even

though a chronic hormonal deficiency may eventually lead to a premature death.

Aldosterone secretion is increased by (1) activation of the renin–angiotensin–aldosterone system by factors related to a reduction in Na^+ and a fall in blood pressure; and (2) direct stimulation of the adrenal cortex by a rise in plasma K^+ concentration (see Figure 13-22). However, aldosterone secretion is intermingled with extracellular fluid volume, extracellular fluid electrolyte concentration, blood volume, blood pressure, and, in general, renal function. Thus, it is difficult to discuss aldosterone secretion separately from these other factors. In addition to its effect on aldosterone secretion, angiotensin promotes growth of the zona glomerulosa, in a manner similar to the effect of TSH on the thyroid. Adrenocorticotrophic hormone (ACTH) from the anterior pituitary primarily promotes the secretion of cortisol, not aldosterone. Therefore, unlike cortisol regulation, the regulation of aldosterone secretion is largely independent of anterior pituitary control.

Glucocorticoids' metabolic effects

Cortisol, the primary glucocorticoid, plays an important role in carbohydrate, protein, and fat metabolism; executes significant permissive actions for other hormonal activities; and helps people cope with stress.

METABOLIC EFFECTS

The overall effect of cortisol's metabolic actions is to increase the concentration of blood glucose at the expense of protein and fat stores. Specifically, cortisol performs the following functions:

- It stimulates hepatic **gluconeogenesis**, the conversion of non-carbohydrate sources (namely, amino acids) into carbohydrate within the liver (*gluco* means “glucose”; *neo* means “new”; *genesis* means “production”). Cortisol can increase the rate of gluconeogenesis by as much as 10 times. Cortisol accomplishes this by its influence on the enzymes used by the liver to change amino acids to glucose and through its ability to increase mobilization of amino acids from muscle tissue. Between meals or during periods of fasting, when no new nutrients are being absorbed into the blood for use and storage, the glycogen (stored glucose) in the liver tends to become depleted as it is broken down to release glucose into the blood. Gluconeogenesis is an important factor in replenishing hepatic glycogen stores and thus in maintaining normal blood glucose levels between meals. This is essential because the brain can use only glucose as its metabolic fuel, yet nervous tissue cannot store glycogen to any extent. The concentration of glucose in the blood must therefore be maintained at an appropriate level to adequately supply the glucose-dependent brain with nutrients.
- It inhibits glucose uptake and use by many tissues but not by the brain, thus sparing glucose for use by the brain, which absolutely requires it as a metabolic fuel. This action contributes to the increase in blood glucose concentration brought about by gluconeogenesis.

- It facilitates lipolysis, the breakdown of lipid (fat) stores in adipose tissue, which releases free fatty acids into the blood (*lysis* means “breakdown”). The mobilized fatty acids are available as an alternative metabolic fuel for tissues that can use this energy source in lieu of glucose, thereby conserving glucose for the brain.

PERMISSIVE ACTIONS

Cortisol is extremely important for its permissiveness (p. 214). For example, cortisol must be present in adequate amounts to permit the catecholamines to induce vasoconstriction. A person lacking cortisol, if untreated, may go into circulatory shock in a stressful situation that demands immediate widespread vasoconstriction.

ROLE IN ADAPTATION TO STRESS

Cortisol plays a key role in adaptation to stress. Stress of any kind is one of the major stimuli for increased cortisol secretion. For example, some of the different forms of stress associated with an increase in cortisol include trauma, infection, surgery, extreme heat or cold, any debilitating disease, and fear (e.g., being attacked by a person or animal). Although cortisol's precise role in adapting to stress is not known, consider the following speculative, but plausible, explanation of what might occur if a person is faced with a life-threatening situation and must forgo eating for a period of time. A cortisol-induced shift away from protein and fat stores in favour of expanded carbohydrate stores and increased availability of blood glucose would help protect the brain from malnutrition during the imposed fasting period. Also, the amino acids liberated by protein degradation would provide a readily available supply of building blocks for tissue repair if physical injury occurred. As a result, an increased pool of glucose, amino acids, and fatty acids would be available for use as needed.

ANTI-INFLAMMATORY AND IMMUNOSUPPRESSIVE EFFECTS

When cortisol or synthetic cortisol-like compounds are administered to yield higher-than-physiologic concentrations of glucocorticoids (i.e., *pharmacological levels*), not only are all the metabolic effects magnified but several important new actions not evidenced at normal physiologic levels are seen. The most noteworthy of glucocorticoids' pharmacological effects are *anti-inflammatory* and *immunosuppressive* (p. 471). (Although these actions are traditionally considered to occur only at pharmacologic levels, recent studies suggest cortisol may exert anti-inflammatory effects even at normal physiologic levels.) Synthetic glucocorticoids have been developed that maximize the anti-inflammatory and immunosuppressive effects of these steroids while minimizing the metabolic effects.

Administering large amounts of glucocorticoid inhibits almost every step of the inflammatory response, making these steroids effective drugs in treating conditions in which the inflammatory response itself has become destructive, such as *rheumatoid arthritis*. Glucocorticoids used in this manner do not affect the underlying disease process; they merely suppress the body's response to the disease. Because glucocorticoids also

exert multiple inhibitory effects on the overall immune process, such as “knocking out of commission” the white blood cells responsible for antibody production as well as those that directly destroy foreign cells, these agents have also proved useful in managing various allergic disorders and in preventing organ transplant rejections.

When these steroids are employed therapeutically, they should be used only when warranted and, even then, only sparingly, for several important reasons. First, because they suppress the normal inflammatory and immune responses that form the backbone of the body’s defence system, a glucocorticoid-treated person has limited ability to resist infections. Second, in addition to the anti-inflammatory and immunosuppressive effects readily exhibited at pharmacologic levels, other less desirable effects may also be observed with prolonged exposure to higher-than-normal concentrations of glucocorticoids. These effects include development of gastric ulcers, high blood pressure, atherosclerosis, menstrual irregularities, and bone thinning. Third, high levels of exogenous glucocorticoids act in negative-feedback fashion to suppress the hypothalamus–pituitary axis that drives normal glucocorticoid secretion and maintains the integrity of the adrenal cortex. Prolonged suppression of this axis can lead to irreversible atrophy of the cortisol-secreting cells of the adrenal gland and thus to permanent inability of the body to produce its own cortisol.

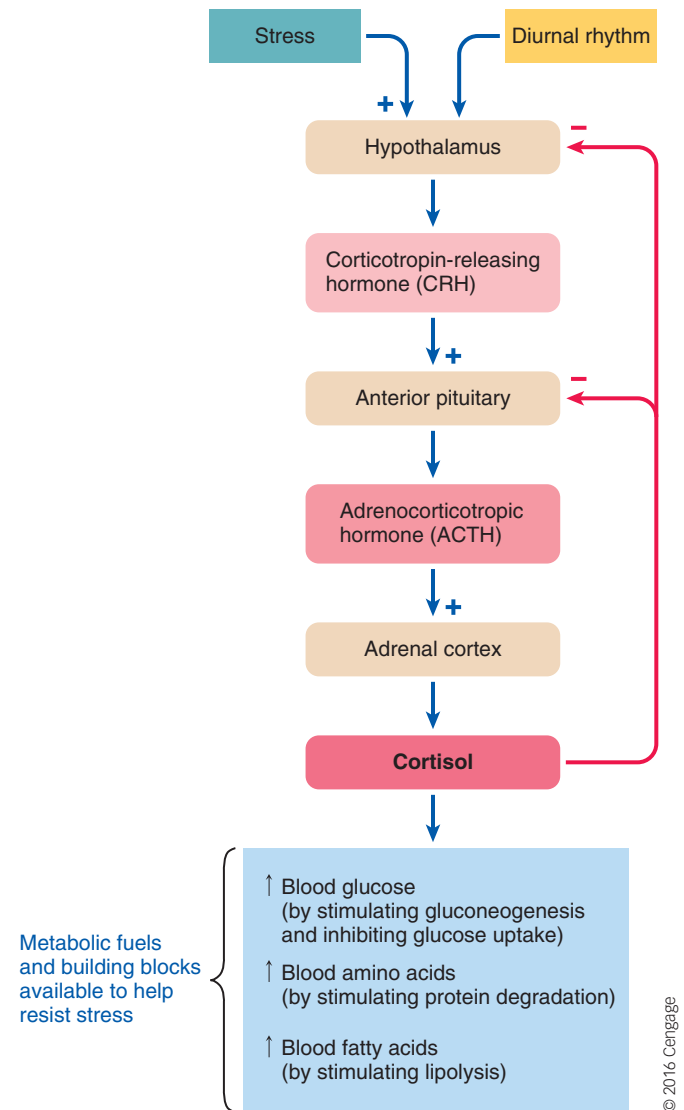

Cortisol secretion

Cortisol secretion by the adrenal cortex is regulated by a negative-feedback system involving the hypothalamus and anterior pituitary (► Figure 6-8). ACTH from the anterior pituitary stimulates the adrenal cortex to secrete cortisol. ACTH is derived from a large precursor molecule, **pro-opiomelanocortin (POMC)**, produced within the endoplasmic reticulum of the anterior pituitary’s ACTH-secreting cells. Prior to secretion, this large precursor is processed into ACTH and several other biologically active peptides, namely, *melanocyte-stimulating hormone (MSH)* and *β-endorphin*, a morphine-like substance. The possible significance of the fact that these multiple secretory products are developed from a single precursor molecule will be addressed later in this section.

Being tropic to the zona fasciculata and zona reticularis, ACTH stimulates both the growth and the secretory output of these two inner layers of the cortex. In the absence of adequate amounts of ACTH, these layers shrink considerably, and cortisol secretion is drastically reduced. Recall that angiotensin, not ACTH, maintains the size of the zona glomerulosa. Like the actions of TSH on the thyroid gland, ACTH enhances many steps in the synthesis of cortisol.

The ACTH-producing cells, in turn, secrete only at the command of corticotropin-releasing hormone (CRH) from the hypothalamus. The feedback control loop is completed by cortisol’s inhibitory actions on CRH and ACTH secretion by the hypothalamus and anterior pituitary, respectively.

The negative-feedback system for cortisol maintains the level of cortisol secretion relatively constant around the set point. Superimposed on the basic negative-feedback control system

► FIGURE 6-8 Control of cortisol secretion

are two additional factors that influence plasma cortisol concentrations by changing the set point: *diurnal rhythm* and *stress*, both of which act on the hypothalamus to vary the secretion rate of CRH.

INFLUENCE OF DIURNAL RHYTHM ON CORTISOL SECRETION

Recall that the plasma cortisol concentration displays a characteristic diurnal rhythm, with the highest level occurring in the morning and the lowest level at night (see Figure 5-3). This diurnal rhythm, which is intrinsic to the hypothalamus–pituitary control system, is related primarily to the sleep–wake cycle. The peak and low levels are reversed in a person who works at night and sleeps during the day. Such time-dependent variations in secretion are of more than academic interest, because it is important clinically to know at what time of day a blood sample was taken when interpreting the significance of a particular value. Also, the linking of cortisol secretion to day–night activity

patterns raises serious questions about the common practice of swing shifts at work (i.e., constantly switching day and night shifts among employees). Furthermore, because cortisol helps a person resist stress, increasing attention is being given to the time of day various surgical procedures are performed.

INFLUENCE OF STRESS ON CORTISOL SECRETION

The other major factor that is independent of, and in fact can override, the stabilizing negative-feedback control is stress. Dramatic increases in cortisol secretion, mediated by the central nervous system through enhanced activity of the CRH–ACTH system, occur in response to all kinds of mentally and physically stressful situations. The magnitude of the increase in plasma cortisol concentration is generally proportional to the intensity of the stressful stimulation; a greater increase in cortisol levels is evoked in response to severe stress than to mild stress.

The adrenal cortex and sex hormones

In both sexes, the adrenal cortex produces both *androgens*, also called male sex hormones, and *estrogens*, also called female sex hormones. The main site of production for the sex hormones is the gonads: the testes for androgens and the ovaries for estrogens. Accordingly, males have a preponderance of circulating androgens, whereas in females estrogens predominate. However, no hormones are unique to either males or females (except those from the placenta during pregnancy), because the adrenal cortex in both sexes produces small amounts of the sex hormone of the opposite sex.

Under normal circumstances, the adrenal androgens and estrogens are not sufficiently abundant or powerful to induce masculinizing or feminizing effects, respectively. The only adrenal sex hormone that has any biological importance is the androgen **dehydroepiandrosterone (DHEA)**. The testes' primary androgen product is the potent testosterone, but the most abundant adrenal androgen is the much weaker DHEA. Adrenal DHEA is overpowered by testicular testosterone in males but is of physiological significance in females, who otherwise lack androgens. This adrenal androgen governs androgen-dependent processes in the female, such as growth of pubic and axillary (armpit) hair, enhancement of the pubertal growth spurt, and development and maintenance of the female sex drive.

Estrogens are normally produced in very small quantities in the adrenal glands because the enzymes required for their production are present in very low concentrations in the adrenocortical cells.

In addition to controlling cortisol secretion, ACTH (not the pituitary gonadotropic hormones) controls adrenal androgen secretion. In general, cortisol and DHEA output by the adrenal cortex follow the same secretion pattern. However, adrenal androgens feedback outside the hypothalamus–pituitary–adrenal cortex loop. Instead of inhibiting CRH, DHEA inhibits gonadotropin-releasing hormone, just as testicular androgens do. Furthermore, sometimes adrenal androgen and cortisol output diverge from each other. For example, at the time of puberty adrenal androgen secretion undergoes a marked surge,

but cortisol secretion does not change. This enhanced secretion initiates the development of androgen-dependent processes in females. In males, the same thing is accomplished primarily by testicular androgen secretion, which is also aroused at puberty. The nature of the pubertal inputs to the adrenals and gonads is still unresolved.

A surge in DHEA secretion begins at puberty and peaks between the ages of 25 and 30. After 30, DHEA secretion slowly tapers off until, by the age of 60, the plasma DHEA concentration is less than 15 percent of its peak level.

Some scientists suspect that the age-related decline of DHEA and other hormones, such as growth hormone (GH) (p. 232) and melatonin (p. 241), plays a role in some problems of aging. Early studies involving DHEA replacement therapy have demonstrated some physical improvement, such as an increase in lean muscle mass and a decrease in fat, but the most pronounced effect was a marked increase in psychological well-being and an improved ability to cope with stress. Advocates for DHEA replacement therapy do not suggest that maintaining youthful levels of this hormone is going to extend the lifespan, but they do propose that it may help people feel and act younger as they age. Other scientists caution that evidence supporting DHEA as an anti-aging therapy is still sparse. Also, they are concerned about DHEA supplementation until it has been thoroughly studied for possible harmful side effects. For example, some research suggests a potential increase in the risk of heart disease among women taking DHEA because of an observed reduction in HDL, the so-called good cholesterol (p. 376). Also, high doses of DHEA have been linked with increased facial hair in women. Furthermore, some experts fear that DHEA supplementation may raise the odds of acquiring ovarian or breast cancer in women and prostate cancer in men.

Although the U.S. Food and Drug Administration (FDA) banned sales of DHEA as an over-the-counter drug in 1985 because of concerns about very real risks coupled with little proof of benefits, the product is available today as an unregulated food supplement. DHEA can be marketed as a dietary supplement without approval by the U.S. FDA as long as the product label makes no specific medical claims. Health Canada, however, classifies DHEA as a controlled substance, available only by prescription.

The adrenal cortex and hormone levels

Although uncommon, there are a number of disorders of adrenocortical function. Excessive secretion may occur with any of the three categories of adrenocortical hormones. Accordingly, three main patterns of symptoms resulting from hyperadrenalism can be distinguished, depending on which hormone type is in excess: (1) aldosterone hypersecretion, (2) cortisol hypersecretion, and (3) adrenal androgen hypersecretion.

ALDOSTERONE HYPERSECRETION

Excess mineralocorticoid secretion may be caused by (1) a hypersecreting adrenal tumour made up of aldosterone-secreting

cells (**primary hyperaldosteronism** or **Conn's syndrome**) or (2) inappropriately high activity of the renin–angiotensin system (**secondary hyperaldosteronism**). The latter may be produced by any number of conditions that cause a chronic reduction in arterial blood flow to the kidneys, thereby excessively activating the renin–angiotensin–aldosterone system. An example is atherosclerotic narrowing of the renal arteries.

The symptoms of both primary and secondary hyperaldosteronism are related to the exaggerated effects of aldosterone—namely, excessive Na^+ retention (*hypernatraemia*) and K^+ depletion (*hypokalaemia*). Also, high blood pressure (hypertension) is generally present, at least partially because of excessive Na^+ and fluid retention.

CORTISOL HYPERSECRETION

Excessive cortisol secretion (**Cushing's syndrome**) can be caused by (1) overstimulation of the adrenal cortex by excessive amounts of CRH and/or ACTH; (2) adrenal tumours that uncontrollably secrete cortisol independent of ACTH; or (3) ACTH-secreting tumours located in places other than the pituitary, most commonly in the lung. Whatever the cause, the prominent characteristics of this syndrome are related to the exaggerated effects of glucocorticoid; the main symptoms are reflections of excessive gluconeogenesis. When too many amino acids are converted into glucose, the body suffers from combined glucose excess (high blood glucose) and protein shortage. Because the resultant hyperglycaemia and glucosuria (glucose in the urine) mimic diabetes mellitus, the condition is sometimes referred to as *adrenal diabetes*. One characteristic of Cushing's syndrome is the mobilization of fat from the lower extremities and the subsequent deposit of that fat into the abdominal and thoracic regions. Another feature of the elevated steroid secretion associated with Cushing's syndrome is oedema of the face. The abnormal fat distribution in the thoracic region—that is, on the back between the shoulder blades—is called a “buffalo hump,” and in the face, is called a “moon face” (► Figure 6-9). The appendages, in contrast, remain thin.

► FIGURE 6-9 Patient with Cushing's syndrome

Besides the effects attributable to excessive glucose production, other effects arise from the widespread mobilization of amino acids from body proteins for use as glucose precursors. Loss of muscle protein leads to muscle weakness and fatigue. The protein-poor, thin skin of the abdomen becomes overstretched by the excessive underlying fat deposits, forming irregular, reddish purple linear streaks. Loss of structural protein within the walls of the small blood vessels leads to easy bruising. Wounds heal poorly, because formation of collagen, a major structural protein found in scar tissue, is depressed. Furthermore, loss of the collagen framework of bone weakens the skeleton, so fractures may result from little or no apparent injury.

ADRENAL ANDROGEN HYPERSECRETION

Excess adrenal androgen secretion, a masculinizing condition, is more common than the extremely rare feminizing condition of excess adrenal estrogen secretion. Either condition is referred to as **adrenogenital syndrome**, emphasizing the pronounced effects that excessive adrenal sex hormones have on the genitalia and associated sexual characteristics.

The symptoms that result from excess androgen secretion depend on the sex of the individual and the age when the hyperactivity first begins.

- *In adult females.* Because androgens exert masculinizing effects, a woman with this disease tends to develop a male pattern of body hair, a condition referred to as **hirsutism**. She usually also acquires other male secondary sexual characteristics, such as deepening of the voice and more muscular arms and legs. The breasts become smaller, and menstruation may cease as a result of androgen suppression of the woman's hypothalamus–pituitary–ovarian pathway for her female sex-hormone secretion.
- *In newborn females.* Female infants born with adrenogenital syndrome manifest male-type external genitalia, because excessive androgen secretion occurs early enough during fetal life to induce development of their genitalia along

male lines, similar to the development of males under the influence of testicular androgen. The clitoris, which is the female homologue of the male penis, enlarges under androgen influence and takes on a penile appearance, so in some cases it is difficult at first to determine the child's sex. Thus, this hormonal abnormality is one of the major causes of **female pseudohermaphroditism**, a condition in which female gonads (ovaries) are present but the external genitalia resemble those of a male. (A true hermaphrodite has the gonads of both sexes.)

- *In prepubertal males.* Excessive adrenal androgen secretion in prepubertal boys causes them to prematurely develop male secondary

sexual characteristics—for example, deep voice, beard, enlarged penis, and sex drive. This condition is referred to as **precocious pseudopuberty** to differentiate it from true puberty, which occurs as a result of increased testicular activity. In precocious pseudopuberty, the androgen secretion from the adrenal cortex is not accompanied by sperm production or any other gonadal activity, because the testes are still in their nonfunctional prepubertal state.

- *In adult males.* Overactivity of adrenal androgens in adult males has no apparent effect, because any masculinizing effect induced by the weak DHEA, even when in excess, is unnoticeable due to the powerful masculinizing effects of the much more abundant and potent testosterone from the testes.

The adrenogenital syndrome is most commonly caused by an inherited enzymatic defect in the cortisol steroidogenic pathway. The pathway for synthesis of androgens branches from the normal biosynthetic pathway for cortisol. When an enzyme specifically essential for synthesis of cortisol is deficient, the result is decreased secretion of cortisol. The decline in cortisol secretion removes the negative-feedback effect on the hypothalamus and anterior pituitary so that levels of CRH and ACTH increase considerably (▶ Figure 6-10). The defective adrenal cortex is incapable of responding to this increased ACTH secretion with cortisol output and instead shunts more of its cholesterol precursor into the androgen pathway. The result is excess DHEA production. This excess androgen does not inhibit ACTH but rather inhibits the gonadotropins. Because gamete production is not stimulated in the absence of gonadotropins, people with adrenogenital syndrome are sterile. Of course, they also exhibit symptoms of cortisol deficiency.

The symptoms of adrenal virilization, sterility, and cortisol deficiency are all reversed by glucocorticoid therapy. Administration of exogenous glucocorticoid replaces the cortisol deficit and, more dramatically, inhibits the hypothalamus and pituitary so that ACTH secretion is suppressed. Once ACTH secretion is reduced, the profound stimulation of the adrenal cortex ceases, and androgen secretion declines markedly. Removing the large quantities of adrenal androgens from circulation allows masculinizing characteristics to gradually recede and normal gonadotropin secretion to resume. Without understanding how these hormonal systems are related, it would be very difficult to comprehend how glucocorticoid administration could dramatically reverse symptoms of masculinization and sterility.

▶ **FIGURE 6-10 Hormonal interrelationships in adrenogenital syndrome.** The adrenocortical cells that are supposed to produce cortisol produce androgens instead because of a deficiency of a specific enzyme essential for cortisol synthesis. Because no cortisol is secreted to act in negative-feedback fashion, CRH and ACTH levels are elevated. The adrenal cortex responds to increased ACTH by further increasing androgen secretion. The excess androgen produces virilization and inhibits the gonadotropin pathway, with the result that the gonads stop producing sex hormones and gametes.

ADRENOCORTICAL INSUFFICIENCY

If one adrenal gland is nonfunctional or removed, the other healthy organ can take over the function of both through hypertrophy and hyperplasia. Therefore, both glands must be affected before adrenocortical insufficiency occurs.

In **primary adrenocortical insufficiency**, also known as **Addison's disease**, all layers of the adrenal cortex are undersecreting. This condition is most commonly caused by autoimmune destruction of the cortex due to erroneous production of adrenal cortex-attacking antibodies, in which case both aldosterone and cortisol are deficient. **Secondary adrenocortical insufficiency** may occur because of a pituitary or hypothalamic abnormality, resulting in insufficient ACTH secretion. In this case, only cortisol is deficient, because aldosterone secretion does not depend on ACTH stimulation.

The symptoms associated with aldosterone deficiency in Addison's disease are the most threatening. If severe enough, the condition is fatal, because aldosterone is essential for life.

However, the loss of adrenal function may develop slowly and insidiously so that aldosterone secretion may be subnormal but not totally lacking. Patients with aldosterone deficiency display K^+ retention (*hyperkalaemia*), caused by reduced K^+ loss in the urine, and Na^+ depletion (*hyponatraemia*), caused by excessive urinary loss of Na^+ . The former disturbs cardiac rhythm. The latter reduces ECF volume, including circulating blood volume, which in turn lowers blood pressure (hypotension).

Symptoms of cortisol deficiency are as would be expected: poor response to stress, hypoglycaemia (low blood glucose) caused by reduced gluconeogenic activity, and lack of permissive action for many metabolic activities. The primary form of the disease also produces hyperpigmentation (darkening of the skin), resulting from excessive secretion of ACTH. Because the pituitary is normal, the decline in cortisol secretion brings about an uninhibited elevation in ACTH output. Recall that both ACTH and melanocyte-stimulating hormone (MSH) are produced from the same large precursor molecule, pro-opiomelanocortin. As a result, levels of MSH and, accordingly, of skin-darkening melanin also rise when the blood levels of ACTH are very high.

We now shift our attention from the adrenal cortex to the adrenal medulla.

The adrenal medulla

The adrenal medulla is actually a modified part of the sympathetic nervous system. Recall that a sympathetic pathway consists of two neurons in sequence—a preganglionic neuron originating in the CNS, whose axonal fibre terminates on a second peripherally located postganglionic neuron, which in turn terminates on the effector organ. The neurotransmitter released by sympathetic postganglionic fibres is norepinephrine, which interacts locally with the innervated organ by binding with specific target receptors known as *adrenergic receptors*.

The adrenal medulla consists of modified postganglionic sympathetic neurons. Unlike ordinary postganglionic sympathetic neurons, those in the adrenal medulla do not have axonal fibres that terminate on effector organs. Instead, on stimulation by the preganglionic fibre, the ganglionic cell bodies within the adrenal medulla release their chemical transmitter directly into the circulation (see Figure 4-43). In this case, the transmitter qualifies as a hormone instead of a neurotransmitter, and once released into circulation the hormones are carried to all body tissues. Like sympathetic fibres, the adrenal medulla does release norepinephrine (about 20 percent of its secretion), but its most abundant secretory output is a similar chemical messenger, known as epinephrine (about 80 percent). The relative contribution of these two hormones will change under different physiological conditions. Both epinephrine and norepinephrine belong to the chemical class of catecholamines, which are derived from the amino acid tyrosine. Epinephrine and norepinephrine are the same, except that epinephrine also has a methyl group.

STORAGE OF CATECHOLAMINES IN CHROMAFFIN GRANULES

Catecholamine is synthesized almost entirely within the cytosol of the adrenomedullary secretory cells. Once produced, epinephrine and norepinephrine are stored in **chromaffin granules**,

which are similar to the transmitter storage vesicles found in sympathetic nerve endings. Segregation of catecholamines in chromaffin granules protects them from being destroyed by cytosolic enzymes during storage.

Clinical Connections

Pheochromocytoma is usually caused by a tumour in the adrenal medulla.

However, in Megan's case, she had a paraganglioma in her celiac ganglia. In this situation, the tumour is also made up of chromaffin cells, so this tumour outside of the adrenal gland is synthesizing and storing catecholamines.

SECRETION OF CATECHOLAMINES FROM THE ADRENAL MEDULLA

Catecholamines are secreted into the blood by exocytosis of chromaffin granules. Their release is analogous to the release mechanism for secretory vesicles that contain stored peptide hormones or the release of norepinephrine at sympathetic postganglionic terminals.

Epinephrine and norepinephrine are generally released by the adrenal medulla at the same time. However, epinephrine is produced exclusively by the adrenal medulla, and the bulk of norepinephrine is produced by sympathetic postganglionic fibres. Adrenomedullary norepinephrine is generally secreted in quantities too small to exert significant effects on target cells. Therefore, for practical purposes we can assume that norepinephrine effects are predominantly mediated directly by the sympathetic nervous system and that epinephrine effects are brought about exclusively by the adrenal medulla.

Epinephrine and norepinephrine

Epinephrine and norepinephrine have varying affinities for the two major classes of receptors: alpha-adrenergic and beta-adrenergic receptors (Table 6-2). There are three subclasses of beta-adrenergic receptors, β_1 , β_2 , and β_3 , which are functionally different in different tissues. The alpha-adrenergic receptors have two subclasses, α_1 and α_2 , which act presynaptically (α_2) to inhibit the release of norepinephrine or postsynaptically (α_1) to stimulate or inhibit the activity at various potassium channels. Most sympathetic target cells have α_1 receptors—some have only α_2 receptors, some only β_2 , and some have both α_1 and β_2 , while β_1 receptors are found almost exclusively in the heart. In general, the responses elicited by activation of α_1 and β_1 receptors are excitatory, whereas the responses to stimulation of α_2 and β_2 receptors are typically inhibitory.

Norepinephrine binds predominantly with α_1 and β_1 receptors located near postganglionic sympathetic-fibre terminals. Hormonal epinephrine, which can reach all α and β_1 receptors via its circulatory distribution, interacts with these same receptors with approximately the same potency as the neurotransmitter norepinephrine (although norepinephrine has a greater affinity than epinephrine for α receptors). Thus, epinephrine and norepinephrine exert similar effects in many tissues, with epinephrine generally reinforcing sympathetic nervous activity. In addition, epinephrine activates β_2 receptors, over which the sympathetic nervous system exerts little influence.

TABLE 6-2 Adrenergic Receptor Types and Responses Elicited by Norepinephrine (NE) and Epinephrine (E)

Adrenergic Receptor Type	Location	Affinity of Catecholamine for NE and E	Typical Response Elicited	Examples of Responses Elicited
α_1	Most sympathetic target cells	NE > E	Excitatory	Generalized arteriolar vasoconstriction ($\uparrow$ smooth muscle contraction)
α_2	Digestive system	NE < E	Inhibitory	Decreased motility in digestive tract ($\downarrow$ smooth muscle contraction)
β_1	Heart	NE = E	Excitatory	Increased rate and strength of cardiac muscle contraction
β_2	Skeletal muscle; smooth muscle of some blood vessels and organs	E only	Inhibitory	Breakdown of glycogen in skeletal muscle; bronchiolar dilation and arteriolar vasodilation in skeletal muscle and heart ($\downarrow$ smooth muscle contraction)

Many of the essentially epinephrine-exclusive β_2 receptors are located at tissues not even supplied by the sympathetic nervous system but reached by epinephrine through the blood. An example is skeletal muscle, where epinephrine exerts metabolic effects such as promoting the breakdown of stored glycogen.

Sometimes epinephrine, through its exclusive β_2 -receptor activation, brings about a different action from that elicited by norepinephrine and epinephrine action through their mutual activation of other adrenergic receptors. As an example, norepinephrine and epinephrine bring about a generalized vasoconstrictor effect that's mediated by α_1 -receptor stimulation. By contrast, epinephrine promotes vasodilation of the blood vessels that supply skeletal muscles and the heart through β_2 -receptor activation.

Epinephrine functions only at the bidding of the sympathetic nervous system, however, which is solely responsible for stimulating its secretion from the adrenal medulla. Epinephrine secretion always accompanies a generalized sympathetic nervous system discharge, so sympathetic activity directly controls actions of epinephrine. By having the more versatile circulating epinephrine at its call, the sympathetic nervous system has a means of reinforcing its own neurotransmitter effects, plus a way of executing additional actions on tissues that it does not directly innervate.

Epinephrine and the sympathetic nervous system

Adrenomedullary hormones are not essential for life, but virtually all organs in the body are affected by these catecholamines. They play important roles in mounting stress responses, regulating arterial blood pressure, and controlling fuel metabolism. The following sections discuss epinephrine's major effects, which it achieves either in collaboration with the sympathetic transmitter norepinephrine or alone to complement direct sympathetic responses.

EFFECTS ON ORGAN SYSTEMS

Together, the sympathetic nervous system and adrenomedullary epinephrine mobilize the body's resources to support peak physical exertion in emergency or stressful situations. The sympathetic and epinephrine actions constitute a fight-or-flight response that prepares a person to combat an enemy or flee from danger (p. 191). Specifically, the sympathetic system and epinephrine increase the rate and strength of cardiac contraction, which increases cardiac output, and their generalized vasoconstrictor effects increase total peripheral resistance. Together, these effects raise arterial blood pressure, thus ensuring an appropriate driving pressure to force blood to the organs most vital for meeting the emergency. Meanwhile, vasodilation of coronary and skeletal muscle blood vessels induced by epinephrine and local metabolic factors shifts blood to the heart and skeletal muscles from other vasoconstricted regions of the body.

In addition, due to their profound influence on the heart and blood vessels, the sympathetic system and epinephrine play an important role in the ongoing maintenance of arterial blood pressure. This is explained in detail in Chapter 9.

Epinephrine (but not norepinephrine) dilates the respiratory airways to reduce the resistance encountered in moving air in and out of the lungs. Epinephrine and norepinephrine also reduce digestive activity and inhibit bladder emptying, activities that can be "put on hold" during a fight-or-flight situation.

METABOLIC EFFECTS

Epinephrine exerts some important metabolic effects. In general, epinephrine prompts the mobilization of stored carbohydrate and fat to provide immediately available energy for use as needed to fuel muscular work. Specifically, epinephrine increases the blood glucose level by several different mechanisms. First, it stimulates both hepatic (liver) gluconeogenesis and **glycogenolysis**, the latter being the breakdown of stored glycogen into glucose, which is released into the blood. Epinephrine also stimulates glycogenolysis in skeletal muscles. Because of the

difference in enzyme content between liver and muscle, however, muscle glycogen cannot be converted directly to glucose. Instead, the breakdown of muscle glycogen releases lactic acid into the blood. The liver removes lactic acid from the blood and converts it into glucose, so epinephrine's actions on skeletal muscle indirectly help raise blood glucose levels. Epinephrine and the sympathetic system may further add to this hyperglycaemic effect by inhibiting the secretion of insulin, the pancreatic hormone primarily responsible for removing glucose from the blood, and by stimulating glucagon, another pancreatic hormone that promotes hepatic glycogenolysis and gluconeogenesis. In addition to increasing blood glucose levels, epinephrine also increases the level of blood fatty acids by promoting lipolysis.

Epinephrine's metabolic effects are appropriate for fight-or-flight situations. The resulting elevated levels of glucose and fatty acids provide additional fuel to power the muscular movement required by the situation and also assure adequate nourishment for the brain during the crisis when no new nutrients are being consumed. Muscles can use fatty acids for energy production, but the brain cannot.

Because of its other widespread actions, epinephrine also increases the overall metabolic rate. Under the influence of epinephrine, many tissues metabolize faster. For example, the work of the heart and respiratory muscles increases, and the pace of liver metabolism steps up. Thus, epinephrine as well as thyroid hormone can increase the metabolic rate.

OTHER EFFECTS

Epinephrine affects the central nervous system to promote a state of arousal and increased CNS alertness. This permits the "quick thinking" that helps a person cope with an impending emergency. Many drugs used as stimulants or sedatives exert their effects by altering catecholamine levels in the CNS.

Both epinephrine and norepinephrine cause sweating, which helps the body rid itself of extra heat generated by increased muscular activity. Also, epinephrine acts on smooth muscles within the eyes to dilate the pupil and flatten the lens. These actions adjust the eyes for more encompassing vision so that the whole threatening scene can be quickly viewed.

Clinical Connections

Because Megan's tumour was secreting catecholamines, all of her symptoms were related to what is called catecholamine excess. Under normal circumstances, the adrenal medulla releases catecholamines when the sympathetic nervous system is activated, and this acts as an amplifier of the signal. However, catecholamine-secreting tumours can act independently, causing sudden, large increases of circulating catecholamines. A key diagnostic test for pheochromocytoma involves looking for elevated urinary output of catecholamine metabolites over a 24-hour period.

Sympathetic stimulation of the adrenal medulla

Catecholamine secretion by the adrenal medulla is controlled entirely by sympathetic input to the adrenal gland. When the sympathetic system is activated under conditions of fear or

stress, it simultaneously triggers a surge of adrenomedullary catecholamine release. The concentration of epinephrine in the blood may increase up to 300 times the normal concentration, with the amount of epinephrine released depending on the type and intensity of the stressful stimulus.

Because both components of the adrenal gland play an extensive role in responding to stress, this is an appropriate place to pull together the major factors involved in the stress response.

Check Your Understanding 6.2

1. List the three categories of adrenocortical hormones, name the primary hormone in each category, and state the functions of each of these hormones.
2. Discuss the effect of ACTH on the adrenal cortex.
3. Name the two catecholamines secreted by the adrenal medulla, and describe how they are stored and released.

6.3 Integrated Stress Response

Stress is the generalized, nonspecific response of the body to any factor that overwhelms, or threatens to overwhelm, the body's compensatory abilities to maintain homeostasis. Contrary to popular usage, the agent inducing the response is correctly called a *stressor*, whereas *stress* refers to the state induced by the stressor. The following types of noxious stimuli illustrate the range of factors that can induce a stress response: *physical* (trauma, surgery, intense heat or cold); *chemical* (reduced O₂ supply, acid-base imbalance); *physiological* (heavy exercise, haemorrhagic shock, pain); *infectious* (bacterial invasion); *psychological or emotional* (anxiety, fear, sorrow); and *social* (personal conflicts, change in lifestyle).

A general reaction to stress

Different stressors may produce some specific responses characteristic of that stressor. For example, the body's specific response to cold exposure is shivering and skin vasoconstriction, whereas the specific response to bacterial invasion includes increased phagocytic activity and antibody production. In addition to their specific response, however, all stressors produce a similar nonspecific, generalized response (► Figure 6-11). This general set of responses common to exposure to all noxious stimuli is called the **general adaptation syndrome (GAS)**. The stress is first identified by the body, and then both the nervous and endocrine systems (neuroendocrine system) rally a defensive response in order to cope with the emergency (noxious stimuli). GAS is now thought to be well understood, but as with many integrative functions within the human body, there is still much to be discovered. The body reacts to stress first by releasing epinephrine and norepinephrine, and then the glucocorticoid hormone cortisol. The result is a state of intense readiness and mobilization of biochemical resources.

► FIGURE 6-11 Action of a stressor on the body

To appreciate the value of the multifaceted stress response, imagine a primitive cave dweller who has just seen a large wild beast lurking in the shadows. We will consider both the neural and hormonal responses that would take place in this scenario. The body responds in the same way to modern-day stressors. From the preceding discussion, you are familiar with all these responses, so now we focus on how these responses work together.

ROLES OF THE SYMPATHETIC NERVOUS SYSTEM AND EPINEPHRINE IN STRESS

In a fight-or-flight scenario, the sympathetic nervous system (with the assistance of epinephrine from the adrenal medulla) readies the body to respond to the stressful situation. A massive discharge from the sympathetic nervous system prepares the body in various ways for the intense muscular work it needs to perform. It increases

- muscle strength;
- mental activity;

- blood pressure;
- blood flow to essential tissue, while decreasing flow to non-essential tissue; and
- cellular metabolism.

It is this sympathetic stress response that enables a person to respond to strenuous physical or emotional stress. The sympathetic stress response can occur in many emotional situations—for example, during a state of rage or fear. If you are hiking in the woods and come across a bear, your sympathetic system will be immediately heightened, providing the physiological changes listed above. The hypothalamus will be stimulated and that signal will be transmitted down to the spinal cord, providing a massive sympathetic output. If it were not for the sympathetic stress response, it would likely be impossible for you to overcome physical or emotional stress. Simultaneously, the sympathetic system calls forth hormonal reinforcements in the form of a massive outpouring of epinephrine from the adrenal medulla. Epinephrine strengthens sympathetic responses and also reaches places not innervated by the sympathetic system to perform additional functions, such as mobilizing carbohydrate and fat stores.

ROLES OF THE CRH–ACTH–CORTISOL SYSTEM IN STRESS

Besides epinephrine, a number of other hormones are involved in the integrated stress response (■ Table 6-3). The predominant hormonal response is activation of the CRH–ACTH–cortisol system. Recall that cortisol's role in helping the body cope with stress is presumed to be related to its metabolic effects. Cortisol breaks down fat and protein stores while expanding carbohydrate stores and increasing the availability of blood glucose.

■ TABLE 6-3 Major Hormonal Changes during the Integrated Stress Response

Hormone	Change	Purpose Served
Epinephrine	↑	Reinforces the sympathetic nervous system to prepare the body for fight-or-flight; mobilizes carbohydrate and fat energy stores; increases blood glucose and blood fatty acids
CRH–ACTH–Cortisol	↑	Mobilizes energy stores and metabolic building blocks for use as needed; increases blood glucose, blood amino acids, and blood fatty acids ACTH facilitates learning and behaviour; b-endorphin co-secreted with ACTH may mediate analgesia
Glucagon	↑	Act in concert to increase
Insulin	↓	blood glucose and blood fatty acids
Renin–Angiotensin–Aldosterone	↑	Conserve salt and H ₂ O to expand the plasma volume; help sustain blood pressure when acute loss of plasma volume occurs
Vasopressin	↑	Angiotensin II and vasopressin cause arteriolar vasoconstriction to increase blood pressure Vasopressin facilitates learning

From Sherwood, *Human Physiology*, 8E. © 2013 Brooks/Cole, a part of Cengage, Inc. Reproduced by permission. www.cengage.com/permissions

A logical assumption is that the increased pool of glucose, amino acids, and fatty acids is available for use as needed, such as to sustain nourishment to the brain and provide building blocks for repair of damaged tissues.

In addition to the effects of cortisol in the hypothalamus–adrenal cortex axis, ACTH may also play a role in resisting stress. ACTH is one of several peptides that facilitate learning and behaviour. Thus, an increase in ACTH during psychosocial stress may help the body cope more readily with similar stressors in the future by facilitating the learning of appropriate behavioural responses. Furthermore, ACTH is not released alone from its anterior pituitary storage vesicles. Cutting of the large pro-opiomelanocortin precursor molecule yields not only ACTH but also morphine-like β -endorphin, which is co-secreted with ACTH on stimulation by CRH during stress. As a potent endogenous opiate, β -endorphin may exert a role in mediating analgesia (reduction of pain perception) if physical injury is inflicted during stress.

ROLE OF OTHER HORMONAL RESPONSES IN STRESS

Besides the CRH–ACTH–cortisol system, other hormonal systems play key roles in the stress response.

- *Elevation of blood glucose and fatty acids through decreased insulin and increased glucagon.* The sympathetic nervous system and the epinephrine secreted under its control both inhibit insulin and stimulate glucagon. These hormonal changes act in concert to elevate blood levels of glucose and fatty acids. Epinephrine and glucagon, whose blood levels are elevated during stress, promote hepatic glycogenolysis and (along with cortisol) hepatic gluconeogenesis. However, insulin, whose secretion is suppressed during stress, opposes the breakdown of liver glycogen stores. All these effects help increase the concentration of blood glucose. The primary stimulus for insulin secretion is a rise in blood glucose; in turn, a primary effect of insulin is to lower blood glucose. If it were not for the deliberate inhibition of insulin during the stress response, the hyperglycaemia caused by stress would stimulate secretion of glucose-lowering insulin. As a result, the elevation in blood glucose could not be sustained. Stress-related hormonal responses also promote a release of fatty acids from fat stores, because lipolysis is favoured by epinephrine, glucagon, and cortisol, but opposed by insulin.
- *Maintenance of blood volume and blood pressure through increased renin–angiotensin–aldosterone and vasopressin activity.* In addition to the hormonal changes that mobilize energy stores during stress, other hormones are simultaneously called into play to sustain blood volume and blood pressure during the emergency. The sympathetic system and epinephrine play major roles in acting directly on the heart and blood vessels to improve circulatory function. In addition, the renin–angiotensin–aldosterone system is activated as a consequence of a sympathetically induced reduction of blood supply to the kidneys (p. 576). Vasopressin secretion is also increased during stressful situations (p. 617). Collectively, these hormones expand the plasma volume by promoting retention of salt and water. Presumably, the enlarged plasma volume serves as a protective measure to

help sustain blood pressure should acute loss of plasma fluid occur through haemorrhage or heavy sweating during the impending period of danger. Vasopressin and angiotensin also have direct vasopressor effects, which would be of benefit in maintaining an adequate arterial pressure in the event of acute blood loss (p. 402). Vasopressin is further believed to facilitate learning, which has implications for future adaptation to stress.

Clinical Connections

Megan's diagnosed condition of pheochromocytoma mimics a chronic stress situation.

Due to the elevated circulating catecholamines, heart rate and blood pressure are elevated, energy stores are mobilized to increase plasma glucose, and mental alertness is increased. The primary difference from a normal stress response, however, is that the other hormonal systems typically involved in the integrated stress response are not involved. In this situation, catecholamine release is not under regulatory control, so there is no feedback loop to shut off its inappropriate release.

6

The hypothalamus

Many responses, such as the fight-or-flight response, are directly or indirectly influenced by the hypothalamus (► Figure 6-12). The hypothalamus receives and coordinates many inputs, including seasonal and circadian rhythms, complex patterns of neuroendocrine outputs, complex homeostatic mechanisms, and many important stereotyped behaviours. The hypothalamus—a very complex brain region—responds to signals generated both externally and internally. It receives input concerning physical and emotional stressors from virtually all areas of the brain and from many receptors throughout the body. In response, the hypothalamus directly activates the sympathetic nervous system, secretes CRH to stimulate ACTH and cortisol release, and triggers the release of vasopressin. Sympathetic stimulation, in turn, brings about the secretion of epinephrine, with which it has a conjoined effect on the pancreatic secretion of insulin and glucagon. Furthermore, vasoconstriction of the renal afferent arterioles by the catecholamines indirectly triggers the secretion of renin by reducing the flow of oxygenated blood through the kidneys. Renin, in turn, sets in motion the renin–angiotensin–aldosterone system. In this way, the hypothalamus integrates the responses of both the sympathetic nervous system and the endocrine system during stress.

Chronic psychosocial stressors

Acceleration of cardiovascular and respiratory activity, retention of salt and water, and mobilization of metabolic fuels and building blocks can be of benefit in response to a physical stressor, such as an athletic competition. Most of the stressors in our everyday lives are psychosocial in nature, yet they induce these same magnified responses. Stressors, such as anxiety about an exam, conflicts with loved ones, or impatience while sitting in a traffic jam, can elicit a stress response.

► FIGURE 6-12 Integration of the stress response by the hypothalamus

Although the general stress response of rapid mobilization of body resources is appropriate in the face of real or threatened physical injury, it is generally inappropriate in response to nonphysical stress. If no extra energy is demanded, no tissue is damaged, and no blood lost, body stores are being broken down and fluid retained needlessly, probably to the detriment of the emotionally stressed individual. In fact, there is strong circumstantial evidence for a link between chronic exposure to psychosocial stressors and the development of pathological conditions, such as high blood pressure, although no definitive cause-and-effect relationship has been ascertained. As a result

of “unused” stress responses, could hypertension result from too much sympathetic vasoconstriction? From too much salt and water retention? From too much vasopressin and angiotensin pressor activity? A combination of these? Other factors? Recall that hypertension can develop with prolonged exposure to pharmacologic levels of glucocorticoids. Could longstanding lesser elevations of cortisol, such as might occur in the face of continual psychosocial stressors, do the same thing, only more slowly? Considerable work remains to be done to evaluate the contributions that the stressors in our everyday lives make toward disease production.

6.4 | Endocrine Control of Fuel Metabolism

We have just discussed the metabolic changes that are elicited during the stress response. Now we concentrate on the metabolic patterns that occur in the absence of stress, including the hormonal factors that govern normal metabolism.

Fuel metabolism

The term **metabolism** refers to all the chemical reactions that occur within the cells of the body. Those reactions involving the degradation, synthesis, and transformation of the three classes of energy-rich organic molecules—protein, carbohydrate, and fat—are collectively known as intermediary metabolism or fuel metabolism (■ Table 6-4).

During the process of digestion, large nutrient molecules (**macromolecules**) are broken down into their smaller absorbable subunits as follows: proteins are converted into amino acids, complex carbohydrates into monosaccharides (mainly glucose), and triglycerides (dietary fats) into monoglycerides and free fatty acids. These absorbable units are transferred from the digestive tract lumen into the blood, either directly or by way of the lymph (Chapter 15).

ANABOLISM AND CATABOLISM

These organic molecules are constantly exchanged between the blood and body cells. The chemical reactions in which the organic molecules participate within the cells are categorized into two metabolic processes: anabolism and catabolism (► Figure 6-13). **Anabolism** is the buildup or synthesis of larger organic macromolecules from small organic molecular subunits and is used for cellular repair and growth. Anabolic reactions generally require energy input in the form of ATP. These reactions result in either (1) the manufacture of materials needed by the cell, such as cellular structural proteins or secretory products; or (2) storage of

excess ingested nutrients not immediately needed for energy production or needed as cellular building blocks. Storage is in the form of glycogen (the storage form of glucose) or fat reservoirs.

Catabolism is the breakdown, or degradation, of large, energy-rich organic molecules within cells. Catabolism encompasses two levels of breakdown: (1) hydrolysis (p. 647) of large cellular organic macromolecules into their smaller subunits, similar to the process of digestion except that the reactions take place within the body cells instead of within the digestive tract lumen (e.g., release of glucose by the catabolism of stored glycogen); and (2) oxidation of the smaller subunits, such as glucose, to yield energy for ATP production (p. 24).

As an alternative to energy production, the smaller, multipotential organic subunits derived from intracellular hydrolysis may be released into the blood. These mobilized glucose, fatty acid, and amino acid molecules can then be used as needed for energy production or cellular synthesis elsewhere in the body.

In an adult, the rates of anabolism and catabolism are generally in balance, so the adult body remains in a dynamic, steady state and appears unchanged even though the organic molecules that determine its structure and function are continuously being turned over. During growth and development, anabolism exceeds catabolism.

INTERCONVERSIONS AMONG ORGANIC MOLECULES

In addition to being able to resynthesize catabolized organic molecules back into the same type of molecules, many cells of the body, especially liver cells, can convert most types of small organic molecules into other types—as in, for example, transforming amino acids into glucose or fatty acids. Because of these interconversions, adequate nourishment can be provided by a wide range of molecules present in different types of foods. There are limits, however. **Essential nutrients**, such as the essential amino acids and vitamins, cannot be formed in the body by conversion from another type of organic molecule and therefore must be consumed in the diet.

■ TABLE 6-4 Summary of Reactions in Fuel Metabolism

Metabolic Process	Reaction	Consequence
Glycogenesis	Glucose → glycogen	↓ Blood glucose
Glycogenolysis	Glycogen → glucose	↑ Blood glucose
Gluconeogenesis	Amino acids → glucose	↑ Blood glucose
Protein Synthesis	Amino acids → protein	↓ Blood amino acids
Protein Degradation	Protein → amino acids	↑ Blood amino acids
Fat Synthesis (Lipogenesis or Triglyceride Synthesis)	Fatty acids and glycerol → triglycerides	↑ Blood fatty acids
Fat Breakdown (Lipolysis or Triglyceride Degradation)	Triglycerides → fatty acids and glycerol	↑ Blood fatty acids

FIGURE 6-13 Summary of the major pathways involving organic nutrient molecules

The major fate of both ingested carbohydrates and fats is catabolism to yield cellular energy. Amino acids are predominantly used for protein synthesis but can be used to supply energy after being converted to carbohydrate or fat by the liver. Thus, all three categories of foodstuff can be used as fuel, and excesses of any foodstuff can be deposited as stored fuel, as you will see shortly.

At a superficial level, fuel metabolism appears relatively simple: The amount of nutrients in the diet must be sufficient to meet the body's needs for energy production and cellular synthesis. This apparently simple relationship is complicated, however, by two important considerations: (1) nutrients taken in at meals must be stored and then released between meals, and (2) the brain must be continuously supplied with glucose. Let us examine the implications of each.

Nutrients storage

Dietary fuel intake is intermittent, not continuous. As a result, excess energy must be absorbed during meals and stored for use during fasting periods between meals, when dietary sources of metabolic fuel are not available (Table 6-5).

- Excess circulating glucose* is stored in the liver and muscle as glycogen, a large molecule consisting of interconnected glucose molecules. The making of these glycogen molecules is an energy-absorbing process (endergonic) under the control of the endocrine system. Because glycogen is a relatively small energy reservoir, less than a day's energy needs can be stored in this form. Once the liver and muscle glycogen stores are filled up, additional glucose is transformed into fatty acids and glycerol, which are used to synthesize

■ TABLE 6-5 Stored Metabolic Fuel in the Body

Metabolic Fuel	Circulating Form	Storage Form	Major Storage Site	Percentage of Total Body Energy Content (and Calories ¹)	Reservoir Capacity	Role
Carbohydrate	Glucose	Glycogen	Liver, muscle	1 (1500)	Less than a day's worth of energy	First energy source; essential for the brain
Fat	Free fatty acids	Triglycerides	Adipose tissue	77 (143 000)	About two months' worth of energy	Primary energy reservoir; energy source during a fast
Protein	Amino acids	Body proteins	Muscle	22 (41 000)	Death results long before capacity is fully used because of structural and functional impairment	Source of glucose for the brain during a fast; last resort to meet other energy needs

© 2016 Cengage

¹Actually refers to kilocalories; see p. 700.

triglycerides (glycerol with three fatty acids attached), primarily in adipose tissue (fat).

- *Excess circulating fatty acids* derived from dietary intake also become incorporated into triglycerides.
- *Excess circulating amino acids* not needed for protein synthesis or during prolonged exercise (such as the amino acids alanine, leucine, and glutamine) are not stored as extra protein but are converted to glucose and fatty acids, which ultimately end up being stored as triglycerides.

As this list shows, the major site of energy storage for excess nutrients of all three classes is adipose tissue. Normally, enough triglyceride is stored to provide energy for about two months, more so in an overweight person. Consequently, during any prolonged period of fasting, the fatty acids released by means of triglyceride catabolism serve as the primary source of energy for most tissues. The catabolism of stored triglycerides frees glycerol as well as fatty acids, but quantitatively speaking, the fatty acids are far more important. Catabolism of stored fat yields 90 percent fatty acids and 10 percent glycerol by weight. Glycerol (but not fatty acids) can be converted to glucose by the liver and contributes in a small way to maintaining blood glucose during a fast.

As amino acids are consumed in our diet, they enter circulation, our bodies' most important amino acid pool (skeletal muscle and liver are the other two pools). Each of these pools is in equilibrium with every other pool, and therefore an increase in amino acid metabolism in one pool affects all other pools. Having these pools of amino acids to draw upon is very beneficial for sustaining life during periods when dietary intake is not consistent.

As a third energy reservoir, a substantial amount of energy is stored as structural protein, primarily in muscle, the most abundant protein mass in the body. Protein is not the first choice to tap as an energy source, however, because it serves other essential

functions; in contrast, the glycogen and triglyceride reservoirs serve solely as energy depots.

The brain and glucose

The second factor complicating fuel metabolism besides intermittent nutrient intake and the resultant necessity of storing nutrients is that the brain normally depends on the delivery of adequate blood glucose as its sole source of energy. Consequently, the blood glucose concentration must be maintained above a critical level. The units of blood glucose monitoring in Canada are reported as mmol glucose/L blood and typically is 5 mmol/L, with a normal range kept within the narrow limits of 4–6 mmol/L. (In contrast, blood glucose concentrations in the United States are given in terms of mass concentration, with a normal level hovering around 90 mg/mL.)

Liver glycogen is an important reservoir for maintaining blood glucose levels during a short fast. However, liver glycogen is depleted relatively rapidly, so during a longer fast other mechanisms must meet the energy requirements of the glucose-dependent brain. First, when no new dietary glucose is entering the blood, tissues not dependent on glucose shift their metabolism to burn fatty acids instead—sparing glucose for the brain. Fatty acids are made available by catabolism of triglyceride stores, as an alternative energy source for tissues that are not glucose dependent. Second, amino acids can be converted to glucose by gluconeogenesis, whereas fatty acids cannot. Once glycogen stores are depleted despite **glucose sparing**, new glucose supplies for the brain are provided by the catabolism of body proteins and conversion of the freed amino acids into glucose.

Amino acids therefore act as precursors for gluconeogenesis during prolonged fasting or starvation. Blood glucose homeostasis is maintained via the glucose-alanine cycle in the liver. Proteins can be broken down to provide approximately

100 grams of glucose per day. During prolonged fasting or starvation, this glucose will be used almost entirely by the brain and nervous system.

The absorptive state and the postabsorptive state

The preceding discussion should make clear that the disposition of organic molecules depends on the body's metabolic state. The two functional metabolic states—the *absorptive state* and the *postabsorptive state*—are related to eating and fasting cycles, respectively (■ Table 6-6).

ABSORPTIVE STATE

After a meal, ingested food (nutrients) is digested and absorbed into circulation. This is an absorptive (fed) state. During this time, carbohydrates absorbed as simple sugars are sent to the liver, where they are converted to glucose. The glucose then travels via circulation to be used as fuel for cellular work, or is converted to glycogen and/or fat.

The glycogen and fat is stored in the liver and adipose tissue, respectively, as reserves for the postabsorptive state. As well, some glucose is stored as glycogen by skeletal muscle cells. Triglycerides in the form of chylomicrons, the primary result of fat digestion from the meal, are first broken down to fatty acids and glycerol through hydrolysis (lipoprotein lipase). Most of these fatty acids are re-formed as triglycerides and stored in adipose tissue. Those not stored are used for energy in the body's cells (e.g., adipose cells, skeletal muscle).

The amino acids absorbed from the protein in the meal enter the primary amino acid pools, to be used for structural purposes. Some of the amino acids (e.g., leucine, alanine, and glutamine) may be used later for fuel, if the body is in a state of fasting or starvation. Excess amino acids are stored as fat, as are excess carbohydrate and fats.

Which fuel source is used as the primary fuel depends on the intensity of the activity being performed. In the absorptive state, when there are plenty of nutrients available, the two primary

fuel sources are fats and carbohydrates. In a resting state, such as when you're sitting and watching TV, the predominant fuel source is fat, followed by carbohydrate. However, as the level of activity (exertion) gradually increases, the choice of fuel gradually changes, from predominantly fat to more carbohydrate. The reason for this change is that carbohydrates are a faster form of fuel than fats, and so they can be used when the demand for energy is greater.

POSTABSORPTIVE STATE

The average meal is absorbed roughly four hours after eating, at which point no nutrients are left in the digestive tract. So, in late morning, late afternoon, or at night when you're sleeping, the body is in a **fasted (postabsorptive) state**. The synthesis of protein and fat is curtailed as the body enters a catabolic state.

During this kind of short-term fasting, endogenous energy stores are mobilized to provide energy. The body looks for other energy sources; for example, it draws on glucose from the liver's glycogen stores and fatty acids from adipose sites. The body, brain, and nerve tissue depend on glucose for metabolism, especially when functioning at greater levels of exertion. Once the body receives its next meal, it will enter a state of anabolism.

However, if the postabsorptive state is prolonged (more than 24 hours), lipolysis becomes the primary source of fuel. This is driven by an increase in β -adrenergic sensitivity and reduced plasma insulin (hypoinsulinaemia). In the initial 24 hours of fasting there is approximately a 35 percent fall in plasma insulin, a corresponding 65 percent increase in lipolysis, and no change in glucose production. After 24 hours of fasting, the rise in lipolysis is likely a proactive mechanism to help protect blood glucose levels, which are primarily maintained by gluconeogenesis.

Note that the blood concentration of nutrients does not fluctuate markedly between the absorptive and postabsorptive states. During the absorptive state, the glut of absorbed nutrients is swiftly removed from the blood and placed into storage; during the postabsorptive state, these stores are catabolized to maintain the blood concentrations at levels necessary to fill tissue energy demands.

■ **TABLE 6-6** Comparison of Absorptive and Postabsorptive States

Metabolic Fuel	Absorptive State	Postabsorptive State
Carbohydrate	Glucose and fat providing major energy source Glycogen synthesis and storage Excess converted and stored as triglyceride fat	Glycogen degradation and depletion Glucose sparing to conserve glucose for the brain Production of new glucose through gluconeogenesis
Fat	Triglyceride synthesis and storage	Triglyceride catabolism Fatty acids providing the major energy source for non-glucose-dependent tissues
Protein	Protein synthesis Excess converted and stored as triglyceride fat	Protein catabolism Amino acids used for gluconeogenesis

Short-term fasting (seven or more days) sets off a starvation response, which encourages the body to store fat once eating is resumed. This is one of the pitfalls of so-called yo-yo dieting. The starvation response is the switching of the body from the use of carbohydrate and fat energy to amino acid and fat energy. The amino acids are synthesized from the amino acid pools (e.g., breakdown of muscle tissue). The catabolism of muscle tissue results in a reduction of the basal metabolic rate, as muscle tissue is the largest metabolically active tissue in the human body.

One of the primal effects of fasting was to reduce the body's energy needs during times of scarcity. Today, however, fasting is used as a form of weight loss. Fasting is analogous to turning the idle lower on a car. The problem with using it as a diet aid becomes apparent when food intake increases post-fasting: fewer calories are now required for basal metabolism (basal metabolic rate), and so a greater percentage of incoming calories are now stored as fat.

ROLES OF KEY TISSUES IN METABOLIC STATES

During the alternating absorptive and postabsorptive metabolic states, various tissues play different roles, as summarized here.

- The *liver* plays the primary role in maintaining normal blood glucose levels. It stores glycogen when excess glucose is available, releases glucose into the blood when needed, and is the principal site for metabolic interconversions, such as gluconeogenesis.
- *Adipose tissue* serves as the primary energy storage site and is important in regulating fatty acid levels in the blood.
- *Muscle* is the primary site of amino acid storage and is the major energy user.
- The *brain* normally can use only glucose as an energy source, yet it does not store glycogen, making it mandatory that blood glucose levels be maintained.

Lesser energy sources

Several other organic intermediates play a lesser role as energy sources—namely, glycerol, lactic acid, and ketone bodies.

- As mentioned earlier, *glycerol* derived from triglyceride hydrolysis (it is the backbone to which the fatty acid chains are attached) can be converted to glucose by the liver.
- Similarly, *lactic acid*, which is produced by the incomplete catabolism of glucose via glycolysis in muscle (p. 24), can also be converted to glucose in the liver.
- **Ketone bodies** are a group of compounds produced by the liver during glucose sparing. Unlike other tissues, when the liver uses fatty acids as an energy source, it oxidizes them only to acetyl coenzyme A (acetyl CoA), which it is unable to process through the citric acid cycle for further energy extraction. Thus, the liver does not degrade fatty acids all the way to carbon dioxide and water for maximum energy release. Instead, it partially extracts the available energy and converts the remaining energy-bearing acetyl CoA molecules into ketone bodies, which it releases into the blood. Ketone bodies serve as an alternative energy source for tissues capable of oxidizing them further by means of the citric acid cycle.

During long-term starvation, the brain starts using ketones instead of glucose as a major energy source. Because death resulting from starvation is usually due to protein wasting rather than hypoglycaemia (low blood glucose), prolonged survival without any caloric intake requires that gluconeogenesis be kept to a minimum as long as the energy needs of the brain are not compromised. A sizable portion of cell protein can be catabolized without serious cellular malfunction, but a point is finally reached at which a cannibalized cell can no longer function adequately. To ward off the fatal point of failure as long as possible during prolonged starvation, the brain starts using ketones as a major energy source, correspondingly decreasing its use of glucose. Use by the brain of this fatty acid “table scrap” left over from the liver’s “meal” limits the necessity of mobilizing body proteins for glucose production to nourish the brain.

Both the major metabolic adaptations to prolonged starvation—a decrease in protein catabolism and use of ketones by the brain—are attributable to the high levels of ketones in the blood at the time. The brain uses ketones only when blood ketone level is high. The high blood levels of ketones also directly inhibit protein degradation in muscle. Thus, ketones spare body proteins while satisfying the brain’s energy needs.

Insulin and glucagon

How does the body know when to shift its metabolic gears from a system of net anabolism and nutrient storage to one of net catabolism and glucose sparing? The flow of organic nutrients along metabolic pathways is influenced by a variety of hormones, including insulin, glucagon, epinephrine, cortisol, and growth hormone. Under most circumstances, the pancreatic hormones, insulin and glucagon, are the dominant hormonal regulators that shift the metabolic pathways back and forth from net anabolism to net catabolism and glucose sparing, depending on whether the body is in a state of feasting or fasting, respectively.

ISLETS OF LANGERHANS

The **pancreas** is an organ composed of both exocrine and endocrine tissues. The exocrine portion secretes a watery, alkaline solution and digestive enzymes through the pancreatic duct into the digestive tract lumen. Scattered throughout the pancreas between the exocrine cells are clusters, or islands, of endocrine cells known as the **islets of Langerhans** (see Figure 15-11). The most abundant pancreatic endocrine cells are the **β (beta) cells**, the site of *insulin* synthesis and secretion, and the **α (alpha) cells**, which produce *glucagon*. Less common are the **δ (delta) cells**, the pancreatic site of *somatostatin* synthesis. The least common islet cells, the **PP cells**, secrete *pancreatic polypeptide*, which plays a possible role in reducing appetite and food intake; these cells will not be discussed further. Here we first highlight somatostatin, and then we examine insulin and glucagon, the most important hormones in the regulation of fuel metabolism.

SOMATOSTATIN

Pancreatic somatostatin inhibits the digestive system in a variety of ways, the overall effect of which is to inhibit digestion of nutrients and to decrease nutrient absorption. Somatostatin is released

from the pancreatic δ cells in direct response to an increase in blood glucose and blood amino acids during absorption of a meal. By exerting its inhibitory effects, pancreatic somatostatin acts in negative-feedback fashion to slow down the rate at which the meal is digested and absorbed, thereby preventing excessive plasma levels of nutrients. Pancreatic somatostatin may also play a paracrine role in regulating pancreatic hormone secretion. The local presence of somatostatin decreases the secretion of insulin, glucagon, and somatostatin itself, but the importance of this function has not been determined.

Somatostatin is also produced by cells lining the digestive tract, where it acts locally as a paracrine to inhibit most digestive processes (p. 664). Furthermore, somatostatin (alias GHIH) is produced by the hypothalamus, where it inhibits the secretion of growth hormone and TSH (p. 229).

Insulin and blood glucose, fatty acid, and amino acid levels

Insulin is a small protein composed of two amino acid chains that are connected to each other by linkages. These two protein chains of insulin are synthesized in the β cells of the pancreas. Insulin has been primarily associated with blood sugar and/or carbohydrates and their storage. However, insulin's effect goes far beyond carbohydrates, as it influences fats and proteins as well. Insulin is associated with a wealth of energy, especially carbohydrates. It lowers the blood levels of glucose, fatty acids, and amino acids and promotes their storage. As these nutrient molecules enter the blood during the absorptive state, insulin promotes their cellular uptake and conversion into glycogen, triglycerides, and protein, respectively. Insulin exerts its many effects either by altering transport of specific blood-borne nutrients into cells or by altering the activity of the enzymes involved in specific metabolic pathways.

The following section describes the effects of insulin on carbohydrates, fats, and proteins, and gives special attention to six forms of glucose transporters that facilitate the movement of blood glucose into specific tissues as needed. We also discuss the relationship between insulin levels and exercise.

ACTIONS ON CARBOHYDRATES

The maintenance of blood glucose homeostasis is a particularly important function of the pancreas. Circulating glucose concentrations are determined by the balance among the following processes (► Figure 6-14): glucose absorption from the digestive tract, transport of glucose into cells, hepatic glucose production, and (abnormally) urinary excretion of glucose.

Insulin exerts four effects that lower blood glucose levels and promote carbohydrate storage:

1. Insulin facilitates glucose transport into most cells.
2. Insulin stimulates **glycogenesis**, the production of glycogen from glucose, in both skeletal muscle and the liver.
3. Insulin inhibits glycogenolysis, the breakdown of glycogen into glucose; in so doing, it favours carbohydrate storage and decreases glucose output by the liver.
4. Insulin further decreases hepatic glucose output by inhibiting gluconeogenesis, the conversion of amino acids into glucose in the liver; it does so by decreasing the amount of amino acids in the blood available to the liver for gluconeogenesis and by inhibiting the hepatic enzymes required for converting amino acids into glucose.

In these four ways, insulin decreases the concentration of blood glucose by promoting the cells' uptake of glucose from the blood for use and storage, while simultaneously blocking the two mechanisms by which the liver releases glucose into the blood (glycogenolysis and gluconeogenesis). Insulin is the only hormone capable of lowering the blood glucose level. Insulin

► **FIGURE 6-14** Factors that affect blood glucose concentration

promotes the uptake of glucose by most cells through a process called glucose transporter recruitment, a topic to which we now turn our attention.

Glucose transport between the blood and cells is accomplished by means of a plasma membrane carrier known as a **glucose transporter (GLUT)**. Six forms of glucose transporters have been identified; named in the order they were discovered—GLUT-1, GLUT-2, and so on. These glucose transporters all accomplish passive facilitated diffusion of glucose across the plasma membrane (p. 43) and are distinct from the Na^+ -glucose cotransport carriers responsible for secondary active transport of glucose across the kidney and intestinal epithelia. Each member of the GLUT family performs slightly different functions. For example, *GLUT-1* transports glucose across the blood-brain barrier, *GLUT-2* transfers into the adjacent bloodstream the glucose that has entered the kidney and intestinal cells by means of the cotransport carriers, and *GLUT-3* is the main transporter of glucose into neurons. The glucose transporter responsible for the majority of glucose uptake by most cells of the body is *GLUT-4*, which operates only at the bidding of insulin. Glucose molecules cannot readily penetrate most cell membranes in the absence of insulin, making most tissues highly dependent on insulin for uptake of glucose from the blood and for its subsequent use. GLUT-4 is especially abundant in the tissues that account for the bulk of glucose uptake from the blood during the absorptive state—namely, skeletal muscle and adipose tissue cells.

GLUT-4 is the only type of glucose transporter that responds to insulin. Unlike the other types of GLUT molecules, which are always present in the plasma membranes at the sites where they perform their functions, GLUT-4 in the absence of insulin is excluded from the plasma membrane. Insulin promotes glucose uptake by **transporter recruitment**. Insulin-dependent cells maintain a pool of intracellular vesicles containing GLUT-4. Insulin induces these vesicles to move to the plasma membrane and fuse with it, thereby inserting GLUT-4 molecules into the plasma membrane. In this way, increased insulin secretion promotes a rapid ten- to thirtyfold increase in glucose uptake by insulin-dependent cells. When insulin secretion decreases, these glucose transporters are retrieved from the membrane and returned to the intracellular pool.

Several tissues do not depend on insulin for their glucose uptake—namely, the brain, working muscles, and the liver. The brain, which requires a constant supply of glucose for its minute-to-minute energy needs, is freely permeable to glucose at all times by means of GLUT-1 and GLUT-3 molecules. Skeletal muscle cells do not depend on insulin for their glucose uptake during exercise, even though they are dependent at rest. Muscle contraction triggers the insertion of GLUT-4 into the plasma membranes of exercising muscle cells in the absence of insulin. This fact is important in managing diabetes mellitus (insulin deficiency), as described later. The liver also does not depend on insulin for glucose uptake, because it does not use GLUT-4. However, insulin does enhance the metabolism of glucose by the liver by stimulating the first step in glucose metabolism, the phosphorylation of glucose to form glucose-6-phosphate. The phosphorylation of glucose as it enters the cell keeps the intracellular concentration of “plain” glucose low so that a gradient

favouring the facilitated diffusion of glucose into the cell is maintained.

Insulin also exerts important actions on fat and protein.

ACTIONS ON FAT

Insulin exerts multiple effects to lower blood fatty acids and promote triglyceride storage:

1. It enhances the entry of fatty acids from the blood into adipose tissue cells.
2. It increases the transport of glucose into adipose tissue cells by means of GLUT-4 recruitment. Glucose serves as a precursor for the formation of fatty acids and glycerol, which are the raw materials for triglyceride synthesis.
3. It promotes chemical reactions that ultimately use fatty acids and glucose derivatives for triglyceride synthesis.
4. It inhibits lipolysis (fat breakdown), reducing the release of fatty acids from adipose tissue into the blood.

Collectively, these actions favour removal of fatty acids and glucose from the blood and promote their storage as triglycerides.

ACTIONS ON PROTEIN

Insulin lowers blood amino acid levels and enhances protein synthesis through several effects:

1. It promotes the active transport of amino acids from the blood into muscles and other tissues. This effect decreases the circulating amino acid level and provides the building blocks for protein synthesis within the cells.
2. It increases the rate of amino acid incorporation into protein by stimulating the cells' protein-synthesizing machinery.
3. It inhibits protein degradation.

The collective result of these actions is a protein anabolic effect. For this reason, insulin is essential for normal growth.

SUMMARY OF INSULIN'S ACTIONS

The use of glucose by skeletal muscle depends primarily on two factors: intensity of work or exercise, and the amount of blood glucose. During periods of moderate- to high-intensity exercise, the muscles cells become highly permeable to glucose (GLUT-4), but insulin is not needed to allow the glucose to enter the muscle. As a result of muscle contraction during exercise, the muscle cell itself becomes more permeable to glucose.

In contrast, in the few hours after eating a meal, the muscle cells become much more permeable to glucose, but the permeability is the result of insulin's action on the muscle cell. The pancreas is triggered to secrete large amounts of insulin, which then act on the skeletal muscle to uptake the glucose and perform glycogenesis, and inhibit glycogenolysis (muscle and liver) and gluconeogenesis (liver). As well, the increase in blood insulin level following a meal inhibits the use of fatty acids from adipose sites for energy production. Thus, during moderate- to high-intensity exercise, and in the few hours after a meal, the muscle cells are highly permeable to glucose and they use glucose rather than fats for energy.

In short, insulin primarily exerts its effects by acting on non-working skeletal muscle, the liver, and adipose tissue. It stimulates biosynthetic pathways that lead to increased glucose use, increased carbohydrate and fat storage, and increased protein synthesis. In so doing, this hormone lowers the blood glucose, fatty acid, and amino acid levels. This metabolic pattern is characteristic of the absorptive state. Indeed, insulin secretion rises during this state and shifts metabolic pathways to net anabolism.

When insulin secretion is low, the opposite effects occur. The rate of glucose entry into cells is reduced, and net catabolism occurs rather than net synthesis of glycogen, triglycerides, and protein. This pattern is reminiscent of the postabsorptive state; indeed, insulin secretion is reduced during the postabsorptive state. However, the other major pancreatic hormone, glucagon, also plays an important role in shifting from absorptive to postabsorptive metabolic patterns (see the section Glucagon and Insulin).

EXERCISE, INSULIN, AND EPINEPHRINE

During moderate exercise, blood glucose declines as a result of skeletal muscle uptake of glucose. As noted before, it is not necessary for the pancreas to secrete insulin in order for the skeletal muscle to uptake additional glucose during exercise, as the contraction of the skeletal muscle influences the GLUT-4 receptor facilitating glucose uptake separate from insulin. The suppression of insulin secretion, and thus the decline in blood insulin levels during exercise, is the result of increased epinephrine levels associated with exercise.

Epinephrine has a direct and indirect effect on liver glucose production. The direct effect is the stimulation of glycogenolysis in the liver; the indirect effect is seen in the inhibition of insulin secretion, which removes the inhibitory effect that insulin has on gluconeogenesis in the liver. As well, the decline in circulating insulin reduces glucose uptake by nonexercising muscle tissue and therefore spares glucose for the active muscle tissue and brain.

During more prolonged exercise, there is a decline in blood glucose and insulin, which facilitates lipolysis and the use of free fatty acids by exercising skeletal muscle. However, following intense training (over several months), a homeostatic adjustment in circulating insulin levels occurs. In trained athletes, the blood insulin levels do not decrease to the same extent as before training. Therefore, more typical blood insulin levels are found post-training, which may be associated with more normal blood glucose levels during exercise.

It is likely that increased free fatty acid metabolism and gluconeogenesis result in better control over blood glucose levels, thus not allowing them to decrease to the same extent as prior to training. Training has also been shown to increase the density of GLUT-4 receptors on skeletal muscle, thereby facilitating the uptake of blood glucose for use during exercise. Because glucose is the primary fuel during exercise, this is an important physiological adjustment.

Regulation of blood glucose levels

The primary control of insulin secretion is a direct negative-feedback system between the pancreatic β cells and the concentration of glucose in the blood flowing to them. An elevated blood glucose level, such as during absorption of a meal, directly stimulates the β cells to synthesize and release insulin. The increased insulin, in turn, reduces the blood glucose to normal and promotes the use and storage of this nutrient. Conversely, a fall in blood glucose below normal, such as during fasting, directly inhibits insulin secretion. Lowering the rate of insulin secretion shifts metabolism from the absorptive to the postabsorptive pattern. This simple negative-feedback system can maintain a relatively constant supply of glucose to the tissues without requiring the participation of nerves or other hormones.

In addition to blood glucose concentration, other inputs are involved in regulating insulin secretion, as follows (> Figure 6-15):

- An elevated blood amino acid level, such as after a high-protein meal, directly stimulates the β cells to increase insulin secretion. In negative-feedback fashion, the increased insulin enhances the entry of these amino acids into the cells, lowering the blood amino acid level while promoting protein synthesis.
- Gastrointestinal hormones, secreted by the digestive tract in response to the presence of food, stimulate pancreatic insulin secretion in addition to having direct regulatory effects on the digestive system. Through this control, insulin secretion is increased in “feedforward,” or anticipatory, fashion even before nutrient absorption increases the blood concentration

> FIGURE 6-15 Factors controlling insulin secretion

of glucose and amino acids. Although early studies indicate a role of glucose-dependent insulinotropic peptide (GIP) (p. 693) in this effect, its exact role in humans remains controversial.

- The autonomic nervous system also directly influences insulin secretion. The islets are richly innervated by both parasympathetic (vagal) and sympathetic nerve fibres. The increase in parasympathetic activity that occurs in response to food in the digestive tract stimulates insulin release. This, too, is a feedforward response in anticipation of nutrient absorption. In contrast, sympathetic stimulation and the concurrent increase in epinephrine both inhibit insulin secretion. The fall in insulin level allows the blood glucose level to rise, an appropriate response to the circumstances under which generalized sympathetic activation occurs—namely, stress (fight-or-flight) and exercise. In both these situations, extra fuel is needed for increased muscle activity.

Diabetes mellitus

Diabetes mellitus is by far the most common of all endocrine disorders. The acute symptoms of diabetes mellitus are attributable to inadequate insulin action. Because insulin is the only hormone capable of lowering blood glucose levels, one of the most prominent features of diabetes mellitus is elevated blood glucose levels, or *hyperglycaemia*. Diabetes literally means “siphon” or “running through,” a reference to the large urine volume accompanying this condition. A large urine volume occurs both in diabetes mellitus (a result of insulin insufficiency) and in diabetes insipidus (a result of vasopressin deficiency). *Mellitus* means “sweet”; *insipidus* means “tasteless.” The urine of patients with diabetes mellitus acquires its sweetness from excess blood glucose that spills into the urine, whereas the urine of patients with diabetes insipidus contains no sugar, so it is tasteless. (Aren’t you glad you were not a health professional at the time when these two conditions were distinguished on the basis of the taste of the urine?)

Diabetes mellitus has two major variants, differing in the capacity for pancreatic insulin secretion: *type 1 diabetes*, characterized by a lack of insulin secretion, and *type 2 diabetes*, characterized by normal or even increased insulin secretion but reduced sensitivity of insulin’s target cells to its presence. (For a further discussion of the distinguishing features of these two types of diabetes mellitus, see Concepts, Challenges, and Controversies.)

The acute consequences of diabetes mellitus can be grouped according to the effects of inadequate insulin action on carbohydrate, fat, and protein metabolism. These effects ultimately cause death through a variety of pathways.

CONSEQUENCES RELATED TO EFFECTS ON CARBOHYDRATE METABOLISM

Other than hyperglycaemia, the changes induced by diabetes mellitus are an exaggerated form of low insulin activity characteristic of the postabsorptive metabolic pattern. In the usual fasting state, the blood glucose level is slightly below normal.

Hyperglycaemia—the hallmark of diabetes mellitus—arises from reduced glucose uptake by cells coupled with increased output of glucose from the liver (step 1 in Figure 6-16). As the glucose-yielding processes of glycogenolysis and gluconeogenesis proceed unchecked in the absence of insulin, hepatic output of glucose increases. Because many of the body’s cells cannot use glucose without the help of insulin, paradoxically, an excess of extracellular glucose coincides with a deficiency of intracellular glucose: “starvation in the midst of plenty.” Even though the non-insulin-dependent brain is adequately nourished during diabetes mellitus, further consequences of the disease lead to brain dysfunction, as you will see shortly.

When the blood glucose rises to the level where the amount of glucose filtered exceeds the tubular cells’ capacity for reabsorption, glucose appears in the urine (*glucosuria*) 2. Glucose in the urine exerts an osmotic effect that draws water with it, producing an osmotic diuresis characterized by *polyuria* (frequent urination) 3. The excess fluid lost from the body leads to dehydration 4 which in turn can ultimately lead to peripheral circulatory failure because of the marked reduction in blood volume 5. Circulatory failure, if uncorrected, can lead to death because of low cerebral blood flow 6 or secondary renal failure resulting from inadequate filtration pressure 7. Furthermore, cells lose water as the body becomes dehydrated by an osmotic shift of water from the cells into the hypertonic extracellular fluid 8. Brain cells are especially sensitive to shrinking, so nervous system malfunction ensues 9 (p. 614). Another characteristic symptom of diabetes mellitus is *polydipsia* (excessive thirst) 10 which is actually a compensatory mechanism to counteract the dehydration.

The story is not complete. In intracellular glucose deficiency, appetite is stimulated, leading to *polyphagia* (excessive food intake) 11. Despite increased food intake, however, progressive weight loss occurs from the effects of insulin deficiency on fat and protein metabolism.

CONSEQUENCES RELATED TO EFFECTS ON FAT METABOLISM

Triglyceride synthesis decreases while lipolysis increases, resulting in large-scale mobilization of fatty acids from triglyceride stores 12. The increased blood fatty acids are largely used by the cells as an alternative energy source. Increased liver use of fatty acids results in the release of excessive ketone bodies into the blood, causing *ketosis* 13. Ketone bodies include several different acids, such as acetoacetic acid, that result from incomplete breakdown of fat during hepatic energy production. The developing ketosis leads to progressive metabolic acidosis 14. Acidosis depresses the brain and, if severe enough, can lead to diabetic coma and death 15.

A compensatory measure for metabolic acidosis is increased ventilation to blow off extra, acid-forming carbon dioxide 16. Exhalation of one of the ketone bodies, acetone, causes a “fruity” breath odour that smells like a combination of Juicy Fruit gum and nail polish remover. Sometimes, because of this odour, a passerby may unfortunately mistake a patient collapsed in a diabetic coma for someone passed out in a state of drunkenness. (This situation illustrates the merits of medical alert

© 2016 Cengage

FIGURE 6-16 Acute effects of diabetes mellitus

identification tags.) People with type 1 diabetes are much more prone to develop ketosis than are type 2 diabetics.

CONSEQUENCES RELATED TO EFFECTS ON PROTEIN METABOLISM

The effects of a lack of insulin on protein metabolism result in a net shift toward protein catabolism. The net breakdown of muscle proteins leads to wasting and weakness of skeletal

muscles ¹⁷ and, in child diabetics, a reduction in overall growth. Reduced amino acid uptake coupled with increased protein degradation results in excess amino acids in the blood ¹⁸. The increased circulating amino acids can be used for additional gluconeogenesis, which further aggravates the hyperglycaemia ¹⁹.

You can readily appreciate from this overview that diabetes mellitus is a complicated disease, one that can disturb

carbohydrate, fat, and protein metabolism and also fluid and acid-base balance. It can also have repercussions on the circulatory system, kidneys, respiratory system, and nervous system.

LONG-TERM COMPLICATIONS

In addition to these potential acute consequences of untreated diabetes, which can be explained on the basis of insulin's short-term metabolic effects, numerous long-range complications of this disease frequently occur after 15–20 years, despite treatment to prevent the short-term effects. Chronic complications, which account for the shorter life expectancy of diabetics, primarily involve degenerative disorders of the blood vessels and nervous system. Cardiovascular lesions are the most common cause of premature death in diabetics. Heart disease and strokes occur with greater incidence than in non-diabetics. Because vascular lesions often develop in the kidneys and the retinas of the eyes, diabetes is a leading cause of both kidney failure and blindness in Canada. Impaired delivery of blood to the extremities may cause these tissues to become gangrenous, and toes or even whole limbs may have to be amputated. In addition to circulatory problems, degenerative lesions in nerves lead to multiple neuropathies that result in dysfunction of the brain, spinal cord, and peripheral nerves. The latter is most often characterized by pain, numbness, and tingling, especially in the extremities.

Regular exposure of tissues to excess blood glucose over a prolonged time leads to tissue alterations responsible for the development of these long-term vascular and neural degenerative complications. Thus, to diminish the incidence of these chronic abnormalities, the best management for diabetes mellitus is to continuously keep blood glucose levels within normal limits. However, the blood glucose levels of diabetic patients on traditional therapy typically fluctuate over a broader range than normal, thereby exposing their tissues to moderately elevated blood glucose during a portion of each day. Fortunately, recent advances in understanding and learning how to manipulate underlying molecular defects in diabetes offer the hope that more effective therapies will be developed within this decade to better manage or even cure existing cases, and perhaps to prevent new cases of this devastating disease. (See Concepts, Challenges, and Controversies for current and potential future treatment strategies for diabetes.)

Hypoglycaemia

Let's now look at the opposite of diabetes mellitus, insulin excess, which is characterized by *hypoglycaemia* (low blood glucose) and can arise in two different ways. First, insulin excess can occur in a diabetic patient when too much insulin has been injected for the person's caloric intake and exercise level, resulting in so-called **insulin shock**. Second, blood insulin level may rise abnormally high in a non-diabetic person who has a β cell tumour or whose β cells are overresponsive to glucose, a condition called **reactive hypoglycaemia**. Such β cells overshoot and secrete more insulin than necessary, in response to elevated blood glucose after a high-carbohydrate meal. The excess insulin drives too much glucose into the cells, resulting in hypoglycaemia.

The consequences of insulin excess are primarily manifestations of the effects of hypoglycaemia on the brain. Recall that the brain relies on a continuous supply of blood glucose for its nourishment and that glucose uptake by the brain does not depend on insulin. With insulin excess, more glucose than necessary is driven into the other insulin-dependent cells. The result is a lowering of the blood glucose level so that not enough glucose is left in the blood to be delivered to the brain. In hypoglycaemia, the brain literally starves. The symptoms, therefore, are primarily referable to depressed brain function, which, if severe enough, may rapidly progress to unconsciousness and death. People with overresponsive β cells usually do not become sufficiently hypoglycaemic to manifest these more serious consequences, but they do show milder symptoms of depressed CNS activity.

The true incidence of reactive hypoglycaemia is a subject of intense controversy, because laboratory measurements to confirm the presence of low blood glucose during the time of symptoms have not been performed in most people who have been diagnosed as having the condition. In mild cases, the symptoms of hypoglycaemia, such as tremor, fatigue, sleepiness, and inability to concentrate, are nonspecific. Because these symptoms could also be attributable to emotional problems or other factors, a definitive diagnosis based on symptoms alone is impossible to make.

The treatment of hypoglycaemia depends on the cause. At the first indication of a hypoglycaemic attack with insulin overdose, the diabetic person should eat or drink something sugary. Prompt treatment of severe hypoglycaemia is imperative to prevent brain damage. Note that a diabetic can lose consciousness and die from either diabetic ketoacidotic coma caused by prolonged insulin deficiency or acute hypoglycaemia caused by insulin shock. Fortunately, the other accompanying signs and symptoms differ sufficiently between the conditions to enable medical caretakers to administer appropriate therapy, either insulin or glucose. For example, ketoacidotic coma is accompanied by deep, laboured breathing (in compensation for the metabolic acidosis) and fruity breath (from exhaled ketone bodies), whereas insulin shock is not.

Paradoxically, even though reactive hypoglycaemia is characterized by a low blood glucose level, people with this disorder are treated by limiting their intake of sugar and other glucose-yielding carbohydrates to prevent their β cells from over responding to a high glucose intake. With low carbohydrate intake, the blood glucose does not rise as much during the absorptive state. Because blood glucose elevation is the primary regulator of insulin secretion, the β cells are not stimulated as much with a low-carbohydrate meal as with a typical meal. Accordingly, reactive hypoglycaemia is less likely to occur. Giving a symptomatic individual with reactive hypoglycaemia something sugary temporarily alleviates the symptoms. The blood glucose level is transiently restored to normal so that the brain's energy needs are once again satisfied. However, as soon as the extra glucose triggers further insulin release, the situation is aggravated.

Diabetics and Insulin: Some Have It and Some Don't

THERE ARE TWO DISTINCT TYPES OF DIABETES MELLITUS (see the accompanying table). **Type 1 diabetes mellitus** (formerly referred to as *insulin-dependent* or *juvenile-onset*), which accounts for about 10 percent of all cases of diabetes, is characterized by a lack of insulin secretion. Because their pancreatic β cells secrete no or nearly no insulin, type 1 diabetics require exogenous insulin for survival. Hence, this form of the disease has the alternative name *insulin-dependent diabetes mellitus*. In **type 2 diabetes mellitus** (formerly referred to as *non-insulin-dependent* or *maturity-onset*), insulin secretion may be normal or even increased, but insulin's target cells are less sensitive than normal to this hormone. Ninety percent of diabetics have the type 2 form of the disease. Although either type can first manifest at any age, type 1 is more prevalent in children, whereas type 2 more generally arises in adulthood—hence, the age-related designations of the two conditions.

For information on the prevalence of diabetes in Canada as well as other facts and figures, see The Public Health Agency of Canada's website at <http://www.phac-aspc.gc.ca/cd-mc/diabetes-diabete/index-eng.php>, and the Canadian Diabetes Association's website at <http://www.diabetes.ca/>.

Statistics from 2014 suggest that the number of Canadians 12 years of age and older who have been diagnosed with diabetes is approximately 2 million, or about 6.7 percent of the Canadian population in that age range. However, the rate of diabetes within Canada's Indigenous population was triple that of the general population.

In 2013, diabetes was the sixth leading cause of death in Canada, with 7045 deaths directly associated with the disease. The actual number of deaths for which diabetes was the underlying factor is probably five times as great, since those with diabetes typically die from complications brought on by other conditions (e.g., heart disease, cardiovascular disease).

Although the direct healthcare cost of diabetes in 2015 was approximately \$3 billion, the total economic burden of diabetes is much higher, at \$12.2 billion, as this estimate did not include the cost of missed days of work and complications from other diseases (heart disease). Due to Canada's aging population, it is estimated that the total economic burden of diabetes will rise to over \$16.9 billion annually by 2020.

In 2015, according to the International Diabetes Federation, 415 million people worldwide had diabetes, and this number is expected to increase to 642 million by 2040. Due to this prevalence of diabetes, its huge economic toll, and the fact that it forces a change in lifestyle for affected individuals and places them at increased risk for developing a variety of troublesome and even life-threatening conditions, intensive research is directed toward better understanding and controlling or preventing both types of the disease.

Underlying Defect in Type 1 Diabetes

Type 1 diabetes is an autoimmune process involving the erroneous, selective destruction of the pancreatic β cells by inappropriately activated T lymphocytes (p. 486). The precise cause of this self-destructive immune attack remains unclear. Some individuals have a genetic susceptibility to acquiring type 1 diabetes. Environmental triggers also appear to play an important role, but investigators have not been able to definitively pin down the culprits.

In 2006, a team of doctors from the University of Alberta, led by Dr. Shapiro, Director and Head of the Clinical Islet Transplant Program, had a breakthrough in the battle against type 1 diabetes. The team developed what is known as the Edmonton Protocol, which consisted of a few adjustments to the initial protocol for islet cell transplants. Through the elimination of steroids, which are known for their toxic effect on the insulin-producing β cells, and the use of newly developed immunosuppressive drugs to prevent rejection of the graft cells, a high number of fresh islet cells were maintained. Since this adjustment, a high success rate for treating type 1 diabetes has been achieved.

Underlying Defect in Type 2 Diabetes

Type 2 diabetics do secrete insulin, but the affected individuals exhibit *insulin* resistance. That is, the basic problem in type 2 diabetes is not lack of insulin but reduced sensitivity of insulin's target cells to its presence. Various genetic and lifestyle factors appear important in the development of type 2 diabetes. Obesity is the biggest risk factor; 90 percent of type 2 diabetics are obese.

Many type 2 diabetics have *metabolic syndrome*, or *syndrome X*, as a forerunner of diabetes. **Metabolic syndrome** encompasses a cluster of features that predispose the person to developing type 2 diabetes and atherosclerosis (p. 374). These features include obesity, large waist circumference (i.e., "apple" shapes; p. 708), high triglyceride levels, low HDL (the so-called good cholesterol; p. 376), high blood glucose, and high blood pressure. An estimated 25 percent of the Canadian population has metabolic syndrome.

The ultimate underlying cause of type 2 diabetes remains elusive despite intense investigation, but researchers have identified a number of possible links between obesity and reduced insulin sensitivity. Recent studies indicate that the responsiveness of skeletal muscle and liver to insulin can be modulated by circulating adipokines (hormones secreted by adipose cells). The implicated adipokines are distinct from leptin, the hormone secreted by adipose cells that plays a role in controlling food intake (p. 702). For example, adipose tissue secretes the hormone **resistin**, which promotes insulin resistance by interfering with insulin action. Resistin production increases in obesity. By contrast, **adiponectin**, another adipokine, increases insulin sensitivity by enhancing insulin's effects, but its production is decreased in obesity. Furthermore, free fatty acids released from adipose tissue

can abnormally accumulate in muscle and interfere with insulin action in muscle. Also, evidence suggests that excessive fatty acids can indirectly trigger apoptosis (cell suicide) of β cells.

Early in the development of the disease, the resulting decrease in sensitivity to insulin is overcome by secretion of additional insulin. However, the sustained overtaxing of the pancreas eventually exceeds the reserve secretory capacity of the genetically weak β cells. Even though insulin secretion may be normal or somewhat elevated, symptoms of insulin insufficiency develop because the amount of insulin is still inadequate to prevent significant hyperglycaemia. The symptoms in type 2 diabetes are usually slower in onset and less severe than in type 1 diabetes.

Treatment of Diabetes

The conventional treatment for type 1 diabetes is a controlled balance of regular insulin injections timed around meals, dietary management of the amounts and types of food consumed, and exercise. Insulin is administered by injection, because if it were swallowed, this peptide hormone would be digested by proteolytic enzymes in the stomach and small intestine. Exercise is also useful in managing both types of diabetes, because working muscles are not insulin dependent. Exercising muscles take up and use some of the excess glucose in the blood, reducing the overall need for insulin.

Whereas type 1 diabetics are permanently insulin dependent, dietary control and weight reduction may be all that is necessary to completely reverse the symptoms in type 2 diabetics. Therefore, type 2 diabetes is alternatively known as *non-insulin-dependent diabetes*. Four classes of oral medications are currently available for use if needed for treating type 2 diabetes, in conjunction with a dietary and exercise regime. These pills help the patient's body use its own insulin more effectively, each by a different mechanism, as follows:

1. By stimulating the β cells to secrete more insulin than they do on their own (*sulphonylureas*, e.g., *Glucotrol*)
2. By suppressing the liver's output of glucose (*metformin*, e.g., *Glucophage*)
3. By blocking the enzymes that digest complex carbohydrates, thus slowing glucose absorption into the blood from the digestive tract and thereby blunting the surge of glucose immediately after a meal (*alpha-glycosidase inhibitors*, e.g., *Prandase*)
4. By making muscle and fat cells more receptive to insulin (i.e., by reducing insulin resistance) (*thiazolidinediones*, e.g., *Avandia*)

A new class of drug was recently approved for treating type 2 diabetics, an *incretin mimetic*. **Incretins** are hormones released by the digestive tract that lower blood glucose, such as GIP. Incretin mimetics are drugs that mimic these naturally occurring hormones. The first drug on the market of this type, *Byetta*, mimics the gut-released hormone

glucagon-like peptide 1 (GLP-1). GLP-1 is released from the small intestine L cells in response to food intake and has multiple glucose-lowering effects. GLP-1 itself is too short-lived to be suitable as a drug. Byetta, which is a version of a peptide found in the venom of a poisonous Gila monster, must be injected. Like GLP-1, this drug stimulates insulin secretion by β cells when blood glucose is high, but not when glucose is in the normal range. It also suppresses production of glucose-raising glucagon and slows gastric emptying, thus slowing the rate at which nutrients are digested and absorbed. By promoting satiety, Byetta decreases food intake and in the long term causes weight loss. Animal studies indicate that Byetta even stimulates regeneration of pancreatic β cells.

None of these drugs deliver new insulin to the body, so they cannot replace insulin injections for people with type 1 diabetes. Furthermore, sometimes the weakened β cells of type 2 diabetics eventually burn out and can no longer produce insulin. In such a case, the previously non-insulin-dependent patient must be placed on insulin therapy for life.

New Approaches to Managing Diabetes

Several new approaches are currently available for insulin-dependent diabetics that preclude the need for the one or two insulin injections daily:

- Implanted insulin pumps can deliver a prescribed amount of insulin on a regular basis, but the recipient must time meals with care to match the automatic insulin delivery.
- Pancreas transplants are also being performed more widely now, with increasing success rates. On the downside, recipients of pancreas transplants must take immunosuppressive drugs for life to prevent rejection of their donated organs. Also, donor organs are in short supply.

Current research on several fronts may dramatically change the approach to diabetic therapy in the near future. The following new treatments are on the horizon, most of which do away with the dreaded daily injections:

- Some methods under development circumvent the need for insulin injections by using alternative routes of administration that bypass the destructive digestive tract enzymes. These include the use of inhaled powdered insulin and the use of ultrasound to force insulin into the skin from an insulin-impregnated patch.
- Some researchers are seeking methods to protect swallowed insulin from destruction by the digestive tract, and others have identified a potential oral substitute for insulin—namely, a non-peptide chemical that binds with the insulin receptors and brings about the same intracellular responses as insulin does. Because this insulin mimic is not a protein, it would not be destroyed by the proteolytic digestive enzymes if taken as a pill.

(Continued)

- Another hope is pancreatic islet transplants. Scientists have developed several types of devices that isolate donor islet cells from the recipient's immune system. Such immunoisolation of islet cells would permit use of grafts from other animals, circumventing the shortage of human donor cells. Pig islet cells would be an especially good source, because pig insulin is nearly identical to human insulin.
- Some researchers hope they will be able to coax stem cells to develop into insulin-secreting cells that can be implanted.
- In a related approach, other scientists are turning to genetic engineering in the hope of developing surrogates for pancreatic β cells. An example is the potential reprogramming of the small-intestine endocrine cells that produce glucose-dependent insulinotropic hormone (GIP). Recall that GIP normally promotes insulin release in feedforward fashion when food is in the digestive tract. The goal is to cause these non- β cells to co-secrete both insulin and GIP on feeding.
- Another approach under development is an implanted, glucose-detecting, insulin-releasing "artificial pancreas" that would

continuously monitor the patient's blood glucose level and deliver insulin in response to need.

- On another front, scientists are hopeful of one day developing immunotherapies that specifically block the attack of the immune system against the β cells, thereby curbing or preventing type 1 diabetes.
- Still other investigators are scurrying to further unravel the defective pathways underlying type 2 diabetes, with the goal of finding new therapeutic targets to prevent, halt, or reverse this condition.

■ Comparison of Type 1 and Type 2 Diabetes Mellitus

Characteristic	Type 1 Diabetes	Type 2 Diabetes
Level of Insulin Secretion	None or almost none	May be normal or exceed normal
Typical Age of Onset	Childhood	Adulthood
Percentage of Diabetics	10–20 percent	80–90 percent
Basic Defect	Destruction of β cells	Reduced sensitivity of insulin's target cells
Treatment	Insulin injections; dietary management; exercise	Dietary control and weight reduction; exercise; sometimes oral hypoglycaemic drugs

Glucagon and insulin

Even though insulin plays a central role in controlling metabolic adjustments between the absorptive and postabsorptive states, the secretory product of the pancreatic islet α cells, **glucagon**, is also very important. Many physiologists view the insulin-secreting β cells and the glucagon-secreting α cells as a coupled endocrine system, whose combined secretory output is a major factor in regulating fuel metabolism.

Glucagon affects many of the same metabolic processes that insulin influences, but in most cases glucagon's actions are opposite to those of insulin. The major site of action of glucagon is the liver, where it exerts a variety of effects on carbohydrate, fat, and protein metabolism.

ACTIONS ON CARBOHYDRATE

The overall effects of glucagon on carbohydrate metabolism result in an increase in hepatic glucose production and release and consequently an increase in blood glucose levels. Glucagon exerts its hyperglycaemic effects by decreasing

glycogen synthesis, promoting glycogenolysis, and stimulating gluconeogenesis.

ACTIONS ON FAT

Glucagon also antagonizes the actions of insulin with regard to fat metabolism by promoting fat breakdown and inhibiting triglyceride synthesis. Glucagon enhances hepatic ketone production (**ketogenesis**) by promoting the conversion of fatty acids to ketone bodies. The blood levels of fatty acids and ketones therefore increase under glucagon's influence.

ACTIONS ON PROTEIN

Glucagon inhibits hepatic protein synthesis and promotes degradation of hepatic protein. Stimulation of gluconeogenesis further contributes to glucagon's catabolic effect on hepatic protein metabolism. Glucagon promotes protein catabolism in the liver, but it does not have any significant effect on blood amino acid levels because it does not affect muscle protein, the major protein store in the body.

THE POSTABSORPTIVE STATE

Glucagon, like insulin, is a large string of approximately 29 amino acids. Although both glucagon and insulin are made of amino acids, they have opposite effects on the body. Considering the catabolic effects of glucagon on energy stores, you would be correct in assuming that glucagon secretion increases during the postabsorptive state and decreases during the absorptive state, just the opposite of insulin secretion. In fact, insulin is sometimes referred to as a “hormone of feasting” and glucagon as a “hormone of fasting.” Insulin tends to put nutrients in storage when blood nutrient levels are high, such as after a meal, whereas glucagon promotes catabolism of nutrient stores between meals to keep up the blood nutrient levels, especially blood glucose.

As in insulin secretion, the major factor regulating glucagon secretion is a direct effect of the blood glucose concentration on the **endocrine pancreas**. In this case, the pancreatic α cells increase glucagon secretion in response to a fall in blood glucose. The hyperglycaemic actions of this hormone tend to raise the blood glucose level back to normal. Conversely, an increase in blood glucose concentration, such as after a meal, inhibits glucagon secretion, which tends to drop the blood glucose level back to normal.

Insulin and glucagon: A team

A direct negative-feedback relationship exists between blood glucose concentration and the rates of secretion of both the β cells and the α cells, but with opposite effects. An elevated blood glucose level stimulates insulin secretion but inhibits glucagon secretion, whereas a fall in blood glucose level leads to decreased insulin secretion and increased glucagon secretion (▶ Figure 6-17). Because insulin lowers and glucagon raises blood glucose, the changes in secretion of these pancreatic hormones in response to deviations in blood glucose work together homeostatically to restore blood glucose levels to normal.

Similarly, a fall in blood fatty acid concentration directly inhibits insulin output and stimulates glucagon output by the pancreas, both of which are negative-feedback control mechanisms to restore the blood fatty acid level to normal.

The opposite effects exerted by blood concentrations of glucose and fatty acids on the pancreatic α and β cells are appropriate for regulating the circulating levels of these nutrient molecules because the actions of insulin and glucagon on carbohydrate and fat metabolism oppose one another. However, the effect of blood amino acid concentration on the secretion of insulin and glucagon is a different story. A rise in blood amino acid concentration stimulates *both* insulin and glucagon secretion. Why this seeming paradox, because glucagon does not exert any effect on blood amino acid concentration? The identical effect of high blood amino acid levels on both insulin and glucagon secretion makes sense when you consider the concomitant effects these two hormones have on blood glucose levels (▶ Figure 6-18). For example, during

▶ FIGURE 6-17 Complementary interactions of glucagon and insulin

absorption of a protein-rich meal, if the rise in blood amino acids stimulated only insulin secretion, hypoglycaemia might result. Because little carbohydrate is available for absorption following consumption of a high-protein meal, the amino acid-induced increase in insulin secretion would drive too much glucose into the cells, causing a sudden, inappropriate drop in the blood glucose level. However, the simultaneous increase in glucagon secretion elicited by elevated blood amino acid levels increases hepatic glucose production. Because the hyperglycaemic effects of glucagon counteract the hypoglycaemic actions of insulin, the net result is maintenance of normal blood glucose levels (and prevention of hypoglycaemic starvation of the brain) during absorption of a meal that is high in protein but low in carbohydrates.

Glucagon excess and diabetes mellitus

Clinical Note No known clinical abnormalities are caused by glucagon deficiency or excess per se. However, diabetes mellitus is frequently accompanied by excess glucagon secretion, because insulin is required for glucose to gain entry into the α cells, where it can exert control over glucagon secretion. As a result, diabetics frequently have a high rate of glucagon secretion concurrent with their insulin insufficiency because the elevated blood glucose cannot inhibit glucagon secretion as it normally would. Because glucagon is a hormone that raises blood glucose, its excess intensifies the hyperglycaemia of diabetes mellitus. For this reason, some insulin-dependent diabetics respond best to a combination of insulin and somatostatin therapy. By inhibiting glucagon secretion, somatostatin indirectly helps achieve better reduction of the elevated blood glucose concentration than can be accomplished by insulin therapy alone.

Epinephrine, cortisol, and growth hormone

The pancreatic hormones are the most important regulators of normal fuel metabolism. However, several other hormones exert direct metabolic effects, even though control of their secretion is keyed to factors other than transitions in metabolism between feasting and fasting states (■ Table 6-7).

FIGURE 6-18 Counteracting actions of glucagon and insulin on blood glucose during absorption of a high-protein meal

The stress hormones, epinephrine and cortisol, both increase blood levels of glucose and fatty acids through a variety of metabolic effects. In addition, cortisol mobilizes amino acids by promoting protein catabolism. Neither hormone plays an important role in regulating fuel metabolism under resting conditions, but both are important for the metabolic responses to stress. During long-term starvation, cortisol also seems to help maintain blood glucose concentration.

Growth hormone (GH) has protein anabolic effects in muscle. In fact, this is one of its growth-promoting features. Although GH can elevate the blood levels of glucose and fatty acids, it is normally of little importance to the overall regulation of fuel metabolism. Deep sleep, stress, exercise, and severe hypoglycaemia stimulate GH secretion, possibly to provide fatty acids as an energy source and spare glucose for the brain under these circumstances. GH, like cortisol, appears to help maintain blood glucose concentrations during starvation.

Although thyroid hormone increases the overall metabolic rate and has both anabolic and catabolic actions, changes in thyroid hormone secretion are usually not important for fuel homeostasis, for two reasons. First, control of thyroid hormone secretion is not directed toward maintaining nutrient levels in the blood. Second, the onset of thyroid hormone action is too

slow to have any significant effect on the rapid adjustments required to maintain normal blood levels of nutrients.

Note that, with the exception of the anabolic effects of GH on protein metabolism, all the metabolic actions of these other hormones are opposite to those of insulin. Insulin alone can reduce blood glucose and blood fatty acid levels, whereas glucagon, epinephrine, cortisol, and GH all increase blood levels of these nutrients. These other hormones are therefore considered **insulin antagonists**. Thus, the main reason diabetes mellitus has such devastating metabolic consequences is that no other control mechanism is available to pick up the slack to promote anabolism when insulin activity is insufficient, so the catabolic reactions promoted by other hormones proceed unchecked. The only exception is protein anabolism stimulated by GH.

Check Your Understanding 6.3

1. Define *glycogenesis*, *glycogenolysis*, and *gluconeogenesis*.
2. Describe the metabolic effects of insulin and glucagon.
3. Compare the effect of increased blood glucose on pancreatic β cells and α cells.

■ **TABLE 6-7** Summary of Hormonal Control of Fuel Metabolism

MAJOR METABOLIC EFFECTS					CONTROL OF SECRETION	
Hormone	Effect on Blood Glucose	Effect on Blood Fatty Acids	Effect on Blood Amino Acids	Effect on Muscle Protein	Major Stimuli for Secretion	Primary Role in Metabolism
Insulin	↓ +Glucose uptake +Glycogenesis –Glycogenolysis –Gluconeogenesis	↓ + Triglyceride synthesis –Lipolysis	↓ + Amino acid uptake	↑ +Protein synthesis –Protein degradation	↑ Blood glucose ↑ Blood amino acids	Primary regulator of absorptive and postabsorptive cycles
Glucagon	↑ +Glycogenolysis +Gluconeogenesis –Glycogenesis	↑ +Lipolysis – Triglyceride synthesis	No effect	No effect	↓ Blood glucose ↑ Blood amino acids	Regulation of absorptive and postabsorptive cycles in concert with insulin; protection against hypoglycaemia
Epinephrine	↑ +Glycogenolysis +Gluconeogenesis –Insulin secretion +Glucagon secretion	↑ +Lipolysis	No effect	No effect	Sympathetic stimulation during stress and exercise	Provision of energy for emergencies and exercise

6.5 | Endocrine Control of Calcium Metabolism

Besides regulating the concentration of organic nutrient molecules in the blood by manipulating anabolic and catabolic pathways, the endocrine system regulates the plasma concentration of a number of inorganic electrolytes. As you already know, aldosterone controls sodium (Na^+) and potassium (K^+) concentrations in the ECF. Three other hormones—*parathyroid hormone*, *calcitonin*, and *vitamin D*—control calcium (Ca^{2+}) and phosphate (PO_4^{3-}) metabolism. These hormonal agents concern themselves with regulating plasma Ca^{2+} , and, in the process, plasma PO_4^{3-} is also maintained. Plasma Ca^{2+} concentration is one of the most tightly controlled variables in the body. The need for the precise regulation of plasma Ca^{2+} stems from its critical influence on so many body activities (see Appendix F for reference values).

Plasma Ca^{2+}

About 99 percent of the calcium in the body is in crystalline form within the skeleton and teeth. Of the remaining 1 percent, about 0.9 percent is found intracellularly within the soft tissues; less than 0.1 percent is present in the ECF. Approximately half of the ECF Ca^{2+} is either bound to plasma proteins, and therefore restricted to the plasma, or complexed with PO_4^{3-} and not free to participate in chemical reactions. The other half of the ECF Ca^{2+} is freely diffusible and can readily pass from the plasma into the interstitial fluid and interact with the cells. The free Ca^{2+} in the plasma and interstitial fluid is considered a single pool. Only this free ECF Ca^{2+} is biologically active and subject to regulation; it constitutes less than one-thousandth of the total Ca^{2+} in the body.

This small, free fraction of ECF Ca^{2+} plays a vital role in a number of essential activities, including the following:

1. **Neuromuscular excitability.** Even minor variations in the concentration of free ECF Ca^{2+} can have a profound and immediate impact on the sensitivity of excitable tissues. A fall in free Ca^{2+} results in overexcitability of nerves and muscles; conversely, a rise in free Ca^{2+} depresses neuromuscular excitability. These effects result from the influence of Ca^{2+} on membrane permeability to Na^+ . A decrease in free Ca^{2+} increases Na^+ permeability, with the resultant influx of Na^+ moving the resting potential closer to threshold. Consequently, in the presence of *hypocalcaemia* (low blood Ca^{2+}), excitable tissues may be brought to threshold by normally ineffective physiologic stimuli so that skeletal muscles discharge and contract (go into spasm) “spontaneously” (in the absence of normal stimulation). If severe enough, spastic contraction of the respiratory muscles results in death by asphyxiation. *Hypercalcaemia* (elevated blood Ca^{2+}) is also life threatening, because it causes cardiac arrhythmias and generalized depression of neuromuscular excitability.
2. **Excitation-contraction coupling in cardiac and smooth muscle.** Entry of ECF Ca^{2+} into cardiac and smooth muscle cells, resulting from increased Ca^{2+} permeability in response to an action potential, triggers the contractile mechanism. Calcium is also necessary for

excitation-contraction coupling in skeletal muscle fibres, but in this case the Ca^{2+} is released from intracellular Ca^{2+} stores in response to an action potential. A significant part of the increase in cytosolic Ca^{2+} in cardiac muscle cells also derives from internal stores.

Note that a *rise in cytosolic Ca^{2+}* within a muscle cell causes contraction, whereas an *increase in free ECF Ca^{2+}* decreases neuromuscular excitability and reduces the likelihood of contraction. Unless one keeps this point in mind, it is difficult to understand why low plasma Ca^{2+} levels induce muscle hyperactivity when Ca^{2+} is necessary to switch on the contractile apparatus. We are talking about two different Ca^{2+} pools, which exert different effects.

3. **Stimulus-secretion coupling.** The entry of Ca^{2+} into secretory cells, which results from increased permeability to Ca^{2+} in response to appropriate stimulation, triggers the release of the secretory product by exocytosis. This process is important for the secretion of neurotransmitters by nerve cells and for peptide and catecholamine hormone secretion by endocrine cells.
4. **Maintenance of tight junctions between cells.** Calcium forms part of the intercellular cement that holds particular cells tightly together.
5. **Clotting of blood.** Calcium serves as a cofactor in several steps of the cascade of reactions that lead to clot formation.

In addition to these functions of free ECF Ca^{2+} , intracellular Ca^{2+} serves as a second messenger in many cells and is involved in cell motility and cilia action. Finally, the Ca^{2+} in bone and teeth is essential for the structural and functional integrity of these tissues.

Because of the profound effects of deviations in free Ca^{2+} , especially on neuromuscular excitability, the plasma concentration of this electrolyte is regulated with extraordinary precision. Let's see how.

Control of Ca^{2+} metabolism

Maintaining the proper plasma concentration of free Ca^{2+} differs from the regulation of Na^+ and K^+ in two important ways. Na^+ and K^+ homeostasis is maintained primarily by regulating the urinary excretion of these electrolytes so that controlled output matches uncontrolled input. Although urinary excretion of Ca^{2+} is hormonally controlled, in contrast to Na^+ and K^+ , not all ingested Ca^{2+} is absorbed from the digestive tract; instead, the extent of absorption is hormonally controlled and depends on the Ca^{2+} status of the body. In addition, bone serves as a large Ca^{2+} reservoir that can be drawn on to maintain the free plasma Ca^{2+} concentration within the narrow limits compatible with life should dietary intake become too low. Exchange of Ca^{2+} between the ECF and bone is also subject to hormonal control. Similar in-house stores are not available for Na^+ and K^+ .

Regulation of Ca^{2+} metabolism depends on hormonal control of exchanges between the ECF and three other compartments: bone, kidneys, and intestine. Control of Ca^{2+} metabolism encompasses two aspects:

- First, regulation of **calcium homeostasis** involves the immediate adjustments required to maintain a *constant free plasma Ca^{2+} concentration* on a minute-to-minute basis. This is largely

accomplished by rapid exchanges between bone and ECF and to a lesser extent by modifications in urinary excretion of Ca^{2+} .

- Second, regulation of **calcium balance** involves the more slowly responding adjustments required to maintain a *constant total amount of Ca^{2+} in the body*. Control of Ca^{2+} balance ensures that Ca^{2+} intake is equivalent to Ca^{2+} excretion over the long term (weeks to months). Calcium balance is maintained by adjusting the extent of intestinal Ca^{2+} absorption and urinary Ca^{2+} excretion.

Parathyroid hormone (PTH), the principal regulator of Ca^{2+} metabolism, acts directly or indirectly on all three of these effector sites. It is the primary hormone responsible for maintenance of Ca^{2+} homeostasis and is essential for maintaining Ca^{2+} balance, although vitamin D also contributes in important ways to Ca^{2+} balance. The third Ca^{2+} -influencing hormone, calcitonin, is not essential for maintaining either Ca^{2+} homeostasis or balance. It serves a backup function during the rare times of extreme hypercalcaemia.

We now examine the specific effects of these hormonal systems—calcium homeostasis and calcium balance—on bone, kidneys, and intestines.

Parathyroid hormone and free plasma Ca^{2+} levels

Parathyroid hormone (PTH) is a peptide hormone consisting of 84 amino acids secreted by the **parathyroid glands**. Like aldosterone, PTH is *essential for life*. The overall effect of PTH is to increase the Ca^{2+} concentration of plasma (and, accordingly, of the entire ECF), thereby preventing hypocalcaemia. In the complete absence of PTH, death ensues within a few days, usually because of asphyxiation caused by hypocalcaemic spasm of respiratory muscles. By its actions on bone, kidneys, and intestine, PTH raises plasma Ca^{2+} level when it starts to fall so that hypocalcaemia and its effects are normally avoided. This hormone also acts to lower plasma PO_4^{3-} concentration. We will consider each of these mechanisms, beginning with an overview of bone remodelling and the actions of PTH on bone.

Bone remodelling

Because 99 percent of the body's Ca^{2+} is in bone, the skeleton serves as a storage depot for Ca^{2+} . (See Table 6–8 for other functions of the skeleton.) Bone is a living tissue, composed of an

organic extracellular matrix impregnated with **hydroxyapatite crystals** consisting primarily of precipitated $\text{Ca}_3(\text{PO}_4)_2$ (calcium phosphate) salts. Normally, $\text{Ca}_3(\text{PO}_4)_2$ salts are in solution in the ECF, but the conditions within bone are suitable for these salts to precipitate (crystallize) around the collagen fibres in the matrix. By mobilizing some of these Ca^{2+} stores in bone, PTH raises plasma Ca^{2+} concentration when it starts to fall.

Despite the apparent inanimate nature of bone, its constituents are continually being turned over. **Bone deposition** (formation) and **bone resorption** (removal) normally go on concurrently so that bone is constantly being remodelled, much as people remodel buildings by tearing down walls and replacing them. Through remodelling, the adult human skeleton is completely regenerated an estimated every 10 years. Bone remodelling serves two purposes: (1) it keeps the skeleton appropriately “engineered” for maximum effectiveness in its mechanical uses, and (2) it helps maintain plasma Ca^{2+} level. Let us examine in more detail the underlying mechanisms and controlling factors for each of these purposes.

Recall that three types of bone cells are present in bone. The *osteoblasts* secrete the extracellular organic matrix within which the $\text{Ca}_3(\text{PO}_4)_2$ crystals precipitate. The *osteocytes* are the retired osteoblasts imprisoned within the bony wall they have deposited around themselves. The *osteoclasts* resorb bone in their vicinity by releasing acids that dissolve the $\text{Ca}_3(\text{PO}_4)_2$ crystals and enzymes that break down the organic matrix. Thus, a constant cellular tug-of-war goes on in bone, with bone-forming osteoblasts countering the efforts of the bone-destroying osteoclasts. These construction and demolition crews, working side by side, continuously remodel bone. Throughout most of adult life, the rates of bone formation and bone resorption are about equal, so total bone mass remains fairly constant during this period.

Osteoblasts and osteoclasts both trace their origins to the bone marrow. Osteoblasts are derived from *stromal cells*, a type of connective tissue cell in the bone marrow, whereas osteoclasts differentiate from *macrophages*, which are tissue-bound derivatives of monocytes, a type of white blood cell (p. 444). In a unique communication system, osteoblasts and their immature precursors produce two chemical signals—*RANK ligand* and *osteoprotegerin*—that govern osteoclast development and activity in opposite ways, as follows (see ▶ Figure 6-19):

- **RANK ligand (RANKL)** revs up osteoclast action. (A *ligand* is a small molecule that binds with a larger protein molecule; an example is an extracellular chemical messenger binding with a plasma membrane receptor.) As its name implies, RANK ligand binds to RANK—which stands for *receptor activator of $\text{NF-}\kappa\text{B}$* —a protein receptor on the membrane surface of nearby macrophages. This binding induces the macrophages to differentiate into osteoclasts and helps them live longer by suppressing apoptosis (cell suicide). As a result, bone resorption is stepped up and bone mass decreases.

Osteoprotegerin (OPG), by contrast, suppresses osteoclast development and activity. OPG secreted into the matrix serves as a freestanding decoy receptor that binds with RANKL. By taking RANKL out of action so that it cannot bind with its intended RANK receptors, OPG prevents RANKL from revving

► **FIGURE 6-19** Role of osteoblasts in governing osteoclast development and activity

up osteoclasts' bone-resorbing activity. As a result, the matrix-making osteoblasts outpace the matrix-removing osteoclasts, so bone mass increases. The balance between RANKL and OPG is therefore an important determinant of bone density. If osteoblasts produce more RANKL, the more osteoclast action, the lower the bone mass. If osteoblasts produce more OPG, the less osteoclast action, the greater the bone mass. Importantly, scientists are currently unravelling the influence of various factors on this balance. For example, the female sex hormone estrogen stimulates activity of the OPG-producing gene in osteoblasts, which is one mechanism by which this hormone preserves bone mass.

Mechanical stress

As a child grows, the bone builders of the body keep ahead of the bone destroyers under the influence of GH and IGF-I (pp. 235).

Mechanical stress also tips the balance in favour of bone deposition, causing bone mass to increase and the bones to strengthen. Mechanical factors adjust the strength of bone in response to the demands placed on it. The greater the physical stress and compression to which a bone is subjected, the greater is the rate of bone deposition. For example, the bones of athletes are stronger and more massive than those of sedentary people.

By contrast, bone mass diminishes and the bones weaken when bone resorption gains a competitive edge over bone deposition in response to removal of mechanical stress. For example, bone mass decreases in people who undergo prolonged bed confinement or those in space flight. Early astronauts lost up to 20 percent of their bone mass during their time in orbit. Therapeutic exercises can limit or prevent such loss of bone.

Clinical Note Bone mass also decreases as a person ages. Bone density peaks when a person is in their 30s, and then starts to decline after age 40. By 50–60 years of age, bone resorption often exceeds bone formation. The result is a reduction in bone mass known as **osteoporosis** (porous bones). This bone-thinning condition is characterized by a diminished laying down of organic matrix as a result of reduced osteoblast activity and/or increased osteoclast activity rather than abnormal bone calcification. The underlying cause of osteoporosis is uncertain. Plasma Ca^{2+} and PO_4^{3-} levels are normal, as is PTH. Osteoporosis occurs with greatest frequency in postmenopausal women because of the associated withdrawal of bone-preserving estrogen.

PTH and plasma Ca^{2+}

In addition to the factors geared toward controlling the mechanical effectiveness of bone, throughout our lifespan PTH uses bone as a “bank” from which it withdraws Ca^{2+} as needed to maintain plasma Ca^{2+} level. Parathyroid hormone has two major effects on bone that raise plasma Ca^{2+} concentration. First, it induces a fast Ca^{2+} efflux into the plasma from the small *labile pool* of Ca^{2+} in the bone fluid. Second, by stimulating bone dissolution, it promotes a slow transfer into the plasma of both Ca^{2+} and PO_4^{3-} from the *stable pool* of bone minerals in bone itself. As a result, ongoing bone remodelling is tipped in favour of bone resorption over bone deposition. Let's examine more thoroughly PTH's actions in mobilizing Ca^{2+} from its labile and stable pools in bone.

PTH and Ca^{2+} transfer

Most bone is organized into **osteon** units, each of which consists of a **central canal** surrounded by concentrically arranged **lamellae**. Lamellae are layers of osteocytes entombed within the bone they have deposited around themselves (► Figure 6-20). The osteons typically run parallel to the long axis of the bone. Blood vessels penetrate the bone from either the outer surface or the marrow cavity and run through the central canals. Osteoblasts are present along the outer surface of the bone and along the inner surfaces lining the central canals. Osteoclasts are also located on bone surfaces undergoing resorption. The surface osteoblasts and entombed osteocytes are connected by an extensive network of small, fluid-containing canals, the **canaliculi**, which allow substances to be exchanged between trapped osteocytes

► **FIGURE 6-20 Organization of bone into osteons.** (a) An osteon, the structural unit of most bone, consists of concentric lamellae (layers of osteocytes entombed by the bone they have deposited around themselves) surrounding a central canal. A small blood vessel branch traverses the central canal. (b) A magnification of the lamellae within an osteon. A network of small canals, the canaliculi, interconnects the entombed osteocytes with one another and with the central canal. Long cytoplasmic processes extend from osteocyte to osteocyte within the canaliculi.

and the circulation. These small canals also contain long, filmy cytoplasmic extensions of osteocytes and osteoblasts that are connected to one another, much as if these cells were “holding hands.” The interconnecting cell network, which is called the **osteocytic-osteoblastic bone membrane**, separates the mineralized bone itself from the plasma within the central canals (► Figure 6-21a). The small, labile pool of Ca^{2+} is in the **bone fluid** that lies between this bone membrane and the adjacent bone, both within the canaliculi and along the surface of the central canal.

PTH’s earliest effect is to activate membrane-bound Ca^{2+} pumps located in the plasma membranes of the osteocytes and osteoblasts. These pumps promote movement of Ca^{2+} , without the accompaniment of PO_4^{3-} , from the bone fluid into these cells. From here, this Ca^{2+} is transferred into the plasma within the central canal. Thus, PTH stimulates the transfer of Ca^{2+} from the bone fluid across the osteocytic-osteoblastic bone membrane

into the plasma. Movement of Ca^{2+} out of the labile pool across the bone membrane accounts for the fast exchange between bone and plasma (► Figure 6-21b). Because of the large surface area of the osteocytic-osteoblastic membrane, small movements of Ca^{2+} across individual cells are amplified into large Ca^{2+} fluxes between the bone fluid and plasma.

After Ca^{2+} is pumped out, the bone fluid is replenished with Ca^{2+} from the partially mineralized bone along the adjacent bone surface. Consequently, the fast exchange of Ca^{2+} does not involve resorption of completely mineralized bone, and bone mass is not decreased. Through this means, PTH draws Ca^{2+} out of the “quick-cash branch” of the bone bank and rapidly increases plasma Ca^{2+} level without actually entering the bank (i.e., without breaking down mineralized bone itself). Under normal conditions, this exchange is much more important for maintaining plasma Ca^{2+} concentration than is the slow exchange.

► **FIGURE 6-21** Fast and slow exchanges of Ca^{2+} across the osteocytic-osteoblastic bone membrane.

(a) Entombed osteocytes and surface osteoblasts are interconnected by long cytoplasmic processes that extend from these cells and connect to one another within the canaliculi. This interconnecting cell network, the osteocytic-osteoblastic bone membrane, separates the mineralized bone from the plasma in the central canal. Bone fluid lies between the membrane and the mineralized bone. (b) Fast exchange of Ca^{2+} between the bone and plasma is accomplished by Ca^{2+} pumps in the osteocytic-osteoblastic bone membrane that transport Ca^{2+} from the bone fluid into these bone cells, which transfer the Ca^{2+} into the plasma. Slow exchange of Ca^{2+} between the bone and plasma is accomplished by osteoclast dissolution of bone.

PTH and localized dissolution of bone

Under conditions of chronic hypocalcaemia, such as may occur with dietary Ca^{2+} deficiency, PTH influences the slow exchange of Ca^{2+} between bone itself and the ECF by promoting actual localized dissolution of bone. It does so by stimulating osteoclasts to gobble up bone, increasing the formation of more osteoclasts, and transiently inhibiting the bone-forming activity of osteoblasts. Bone contains so much Ca^{2+} compared with the plasma (more than 1000 times as much) that even when PTH promotes increased bone resorption, there are no immediate discernible effects on the skeleton because such a tiny amount of bone is

affected. Yet the negligible amount of Ca^{2+} borrowed from the bone bank can be lifesaving in terms of restoring free plasma Ca^{2+} level to normal. The borrowed Ca^{2+} is then redeposited in the bone at another time when Ca^{2+} supplies are more abundant. Meanwhile, plasma Ca^{2+} level has been maintained without sacrificing bone integrity. However, prolonged excess PTH secretion over months or years eventually leads to the formation of cavities throughout the skeleton that are filled with very large, overstuffed osteoclasts.

When PTH promotes dissolution of the $\text{Ca}_3(\text{PO}_4)_2$ crystals in bone to harvest their Ca^{2+} content, both Ca^{2+} and PO_4^{3-} are released into the plasma. An elevation in plasma PO_4^{3-} is undesirable, but PTH deals with this dilemma by its actions on the kidneys, a topic to which we now turn our attention.

PTH and the kidneys

Parathyroid hormone stimulates Ca^{2+} conservation and promotes PO_4^{3-} elimination by the kidneys during urine formation. Under the influence of PTH, the kidneys can reabsorb more of the filtered Ca^{2+} , so less Ca^{2+} escapes into urine. This effect increases plasma Ca^{2+} level and decreases urinary Ca^{2+} losses. (It would be counterproductive to dissolve bone to obtain more Ca^{2+} only to lose it in urine.) By contrast, PTH decreases PO_4^{3-} reabsorption, thereby increasing urinary PO_4^{3-} excretion. As a result, PTH reduces plasma PO_4^{3-} levels at the same time as it increases plasma Ca^{2+} concentrations.

This PTH-induced removal of extra PO_4^{3-} from the body fluids is essential for preventing precipitation

of the Ca^{2+} freed from bone. Because of the solubility characteristics of $\text{Ca}_3(\text{PO}_4)_2$ salt, the product of the plasma concentration of Ca^{2+} multiplied by the plasma concentration of PO_4^{3-} must remain roughly constant. Therefore, an inverse relationship exists between the plasma concentrations of Ca^{2+} and PO_4^{3-} . For example, when plasma PO_4^{3-} level rises, some plasma Ca^{2+} is forced back into bone through hydroxyapatite crystal formation, thereby reducing plasma Ca^{2+} level and keeping constant the calcium phosphate product. This inverse relationship occurs because the concentrations of free Ca^{2+} and PO_4^{3-} ions in the ECF are in equilibrium with the bone crystals.

Recall that both Ca^{2+} and PO_4^{3-} are released from bone when PTH promotes bone dissolution. Because PTH is secreted only when plasma Ca^{2+} falls below normal, the released Ca^{2+} is needed to restore plasma Ca^{2+} to normal, yet the released PO_4^{3-} tends to raise plasma PO_4^{3-} levels above normal. If plasma PO_4^{3-} levels were allowed to rise above normal, some of the released Ca^{2+} would have to be redeposited in the bone along with the PO_4^{3-} to keep the $\text{Ca}^{2+}-\text{PO}_4^{3-}$ product constant. This self-defeating redeposition of Ca^{2+} would lower plasma Ca^{2+} , just the opposite of the needed effect. Therefore, PTH acts on the kidneys to decrease the reabsorption of PO_4^{3-} by the renal tubules. This increases urinary excretion of PO_4^{3-} and lowers its plasma concentration, even though extra PO_4^{3-} is released from bone into the blood.

As well as its roles in increasing Ca^{2+} reabsorption and decreasing PO_4^{3-} reabsorption, PTH has a role in enhancing the activation of vitamin D by the kidneys.

PTH and intestinal absorption of Ca^{2+} and PO_4^{3-}

Although PTH has no direct effect on the intestine, it indirectly increases both Ca^{2+} and PO_4^{3-} absorption from the small intestine by helping activate vitamin D. This vitamin, in turn, directly increases intestinal absorption of Ca^{2+} and PO_4^{3-} , a topic we will discuss more thoroughly shortly.

Plasma concentration of free Ca^{2+} : Regulating PTH secretion

All the effects of PTH raise plasma Ca^{2+} levels. Correspondingly, PTH secretion is increased in response to a fall in plasma Ca^{2+} concentration and decreased in response to a rise in plasma Ca^{2+} levels. The secretory cells of the parathyroid glands are directly and exquisitely sensitive to changes in free plasma Ca^{2+} . Because PTH regulates plasma Ca^{2+} concentration, this relationship forms a simple negative-feedback loop that controls PTH secretion without involving any nervous or other hormonal intervention (► Figure 6-22).

Calcitonin and plasma Ca^{2+} concentration

Calcitonin was first purified by Copp and Cheney at the University of British Columbia and thought to be a hormone of the parathyroid gland. However, it was later recognized that this hormone is produced by the C cells of the thyroid gland. Like PTH, calcitonin has two effects on bone, but in this case both effects *decrease* plasma Ca^{2+} levels. First, on a short-term basis, calcitonin decreases Ca^{2+} movement from the bone fluid into the plasma. Second, on a long-term basis, calcitonin decreases bone resorption by inhibiting the activity of osteoclasts. The suppression of bone resorption lowers plasma PO_4^{3-} levels as well as reduces plasma Ca^{2+} concentration. The hypocalcaemic and hypophosphataemic effects of calcitonin are due entirely to this hormone's actions on bone. It has no effect on the kidneys or intestine.

As with PTH, the primary regulator of calcitonin release is free plasma Ca^{2+} concentration. However, in contrast to its effect on PTH release, an increase in plasma Ca^{2+} stimulates calcitonin secretion, and a fall in plasma Ca^{2+} inhibits calcitonin secretion

► FIGURE 6-22 Negative-feedback loops controlling parathyroid hormone (PTH) and calcitonin secretion

(Figure 6-22). Because calcitonin reduces plasma Ca^{2+} levels, this system constitutes a second simple negative-feedback control over plasma Ca^{2+} concentration, one opposed to the PTH system.

Most evidence suggests, however, that calcitonin plays little or no role in the normal control of Ca^{2+} or PO_4^{3-} metabolism. Although calcitonin protects against hypercalcaemia, this condition rarely occurs under normal circumstances. Moreover, neither thyroid removal nor calcitonin-secreting tumours alter circulating levels of Ca^{2+} or PO_4^{3-} , which implies that this hormone is not normally essential for maintaining Ca^{2+} or PO_4^{3-} homeostasis. Calcitonin may, however, play a role in protecting skeletal integrity when there is a large Ca^{2+} demand, such as during pregnancy or breastfeeding. Furthermore, some experts speculate that calcitonin may hasten the storage of newly absorbed Ca^{2+} following a meal. Gastrointestinal hormones secreted during digestion of a meal have been shown to stimulate the release of calcitonin.

Vitamin D and calcium absorption

The final factor involved in regulating Ca^{2+} metabolism is **cholecalciferol (vitamin D)**, a steroid-like compound essential for Ca^{2+} absorption in the intestine. Strictly speaking, vitamin D should be considered a hormone, because the body can produce it in the skin from a precursor related to cholesterol (7-dehydrocholesterol) on exposure to sunlight. It is subsequently released into the blood to act at a distant target site, the intestine. The skin, therefore, is actually an endocrine gland and vitamin D a hormone. Traditionally, however, this chemical messenger has been considered a vitamin, for two reasons. First, it was originally discovered and isolated from a dietary source and tagged as a vitamin. Second, even though the skin would be an adequate source of vitamin D if it were exposed to sufficient sunlight, indoor dwelling and clothing in response to cold weather and social customs preclude significant exposure of the skin to sunlight in Canada and many other parts of the world most of the time. At least part of

the essential vitamin D must therefore be derived from dietary sources.

ACTIVATION OF VITAMIN D

Regardless of its source, vitamin D is biologically inactive when it first enters the blood from either the skin or the digestive tract. It must be activated by two sequential biochemical alterations that involve the addition of two hydroxyl ($-\text{OH}$) groups (► Figure 6-23). The first of these reactions occurs in the liver and the second in the kidneys. The end result is production of the active form of vitamin D, $1,25-(\text{OH})_2$ -vitamin D_3 , also known as *calcitriol*. The kidney enzymes involved in the second step of vitamin D activation are stimulated by PTH in response to a fall in plasma Ca^{2+} . To a lesser extent, a fall in plasma PO_4^{3-} also enhances the activation process.

FUNCTION OF VITAMIN D

The most dramatic effect of activated vitamin D is to increase Ca^{2+} absorption in the intestine. Unlike most dietary constituents, dietary Ca^{2+} is not indiscriminately absorbed by the digestive system. In fact, the majority of ingested Ca^{2+} is typically not absorbed but is lost in the feces. When needed, more dietary Ca^{2+} is absorbed into the plasma under the influence of vitamin D. Independently of its effects on Ca^{2+} transport, the active form of vitamin D also increases intestinal PO_4^{3-} absorption. Furthermore, vitamin D increases the responsiveness of bone to PTH. Thus, vitamin D and PTH are closely interdependent (► Figure 6-24).

PTH is principally responsible for controlling Ca^{2+} homeostasis, because the actions of vitamin D are too sluggish for it to contribute substantially to the minute-to-minute regulation of plasma Ca^{2+} concentration. However, both PTH and vitamin D are essential to Ca^{2+} balance—the process that ensures over the long term that Ca^{2+} input into the body is equivalent to Ca^{2+} output. When dietary Ca^{2+} intake is reduced, the resultant transient fall in plasma Ca^{2+} level stimulates PTH secretion. The increased PTH has two effects important for maintaining Ca^{2+} balance: (1) it stimulates Ca^{2+} reabsorption by the kidneys, thereby decreasing Ca^{2+} output; and (2) it activates vitamin D, which increases the efficiency of uptake of ingested Ca^{2+} . Because PTH also promotes bone resorption, a substantial loss of bone minerals occurs if Ca^{2+} intake is reduced for a prolonged period, even though bone is not directly involved in maintaining the balance of Ca^{2+} input and output.

Recent research indicates that the functions of vitamin D are far-reaching than its effects on uptake of ingested Ca^{2+} and PO_4^{3-} . Vitamin D, at higher blood concentrations than those sufficient to protect bone, appears to bolster muscle strength and is also an important force in energy metabolism and immune health. It helps thwart development of diabetes mellitus, fights some types of cancer, and—by presently unknown mechanisms—counters autoimmune diseases such

► FIGURE 6-23 Activation of vitamin D

as multiple sclerosis. Because of these newly found actions, scientists and dieticians are reevaluating the recommended dietary allowance (RDA) for vitamin D in the diet, especially when sufficient sun exposure is not possible. The RDA will likely be bumped up, but further study is needed to determine the optimal amount.

Phosphate metabolism

Plasma PO_4^{3-} concentration is not as tightly controlled as plasma Ca^{2+} concentration. Phosphate is regulated directly by vitamin D and indirectly by the plasma Ca^{2+} –PTH feedback loop. To illustrate, a fall in plasma PO_4^{3-} concentration exerts a twofold effect to help raise the circulating PO_4^{3-} level back to normal (► Figure 6-25). First, because of the inverse relationship between the PO_4^{3-} and Ca^{2+} concentrations in the plasma, a fall in plasma PO_4^{3-} increases plasma Ca^{2+} , which directly suppresses PTH secretion. In the presence of reduced PTH, PO_4^{3-} reabsorption by the kidneys increases, returning plasma PO_4^{3-} concentration toward normal. Second, a fall in plasma PO_4^{3-} also increases activation of vitamin D, which then promotes PO_4^{3-} absorption

► FIGURE 6-24 Interactions between PTH and vitamin D in controlling plasma calcium

in the intestine. This further helps alleviate the initial hypophosphataemia. Note that these changes do not compromise Ca^{2+} balance. Although the increase in activated vitamin D stimulates Ca^{2+} absorption, the concurrent fall in PTH produces a compensatory increase in urinary Ca^{2+} excretion because less of the filtered Ca^{2+} is reabsorbed.

Disorders in Ca^{2+} metabolism

The primary disorders that affect Ca^{2+} metabolism are too much or too little PTH or a deficiency of vitamin D.

PTH HYPERSECRETION

Excess PTH secretion, or **hyperparathyroidism**, which is usually caused by a hypersecreting tumour in one of the parathyroid glands, is characterized by hypercalcaemia and hypophosphataemia. The affected individual can be asymptomatic or symptoms can be severe, depending on the magnitude of the problem. The following are among the possible consequences:

- Hypercalcaemia reduces the excitability of muscle and nervous tissue, leading to muscle weakness and neurologic

disorders, including decreased alertness, poor memory, and depression. Cardiac disturbances may also occur.

- Excessive mobilization of Ca^{2+} and PO_4^{3-} from skeletal stores leads to thinning of bone, which may result in skeletal deformities and increased incidence of fractures.
- An increased incidence of Ca^{2+} -containing kidney stones occurs because the excess quantity of Ca^{2+} being filtered through the kidneys may precipitate and form stones. These stones may impair renal function. Passage of the stones through the ureters causes extreme pain. Because of these potential multiple consequences, hyperparathyroidism has been called a disease of “bones, stones, and abdominal groans.”
- To further account for the “abdominal groans,” hypercalcaemia can cause digestive disorders, such as peptic ulcers, nausea, and constipation.

PTH HYPOSECRETION

Because of the close anatomic relation between the parathyroid glands and the thyroid, the most common cause of deficient PTH secretion—**hypoparathyroidism**—used to be inadvertent removal of the parathyroid glands (before doctors knew about their existence) during

surgical removal of the thyroid gland (to treat thyroid disease). If all the parathyroid tissue was removed, these patients died, of course, because PTH is essential for life. Physicians were puzzled why some patients died soon after thyroid removal even though no surgical complications were apparent. Now that the location and importance of the parathyroid glands have been discovered, surgeons are careful to leave parathyroid tissue during thyroid removal. Rarely, PTH hyposecretion results from an autoimmune attack against the parathyroid glands.

Hypoparathyroidism leads to hypocalcaemia and hyperphosphataemia. The symptoms are mainly caused by increased neuromuscular excitability from the reduced level of free plasma Ca^{2+} . In the complete absence of PTH, death is imminent because respiratory muscles go into hypocalcaemic spasm. With a relative deficiency rather than a complete absence of PTH, milder symptoms of increased neuromuscular excitability become evident. Muscle cramps and twitches occur from spontaneous activity in the motor nerves, whereas tingling and pins-and-needles sensations result from spontaneous activity in the sensory nerves. Mental changes include irritability and paranoia.

VITAMIN D DEFICIENCY

The major consequence of vitamin D deficiency is impaired intestinal absorption of Ca^{2+} . In the face of reduced Ca^{2+} uptake, PTH maintains the plasma Ca^{2+} level at the expense

FIGURE 6-25 Control of plasma phosphate

of the bones. As a result, the bone matrix is not properly mineralized, because Ca^{2+} salts are not available for deposition. The demineralized bones become soft and deformed, bowing under the pressures of weight bearing, especially in children. This condition is known as **rickets** in children and **osteomalacia** in adults.

Check Your Understanding 6.4

1. Describe the distribution of Ca^{2+} in the body and the functions of free ECF Ca^{2+} .
2. Discuss the effects of PTH on bone, kidneys, and the intestine.
3. Explain the importance of Vitamin D in Ca^{2+} homeostasis.

Chapter in Perspective: Focus on Homeostasis

A number of peripherally located endocrine glands play key roles in maintaining homeostasis, primarily by means of their regulatory influences over the rate of various metabolic reactions and over electrolyte balance. These endocrine glands all secrete hormones in response to specific stimuli. The hormones, in turn, exert effects that act in negative-feedback fashion to resist the change that induced their secretion, thus maintaining stability in the internal environment. The specific contributions of the peripheral endocrine glands to homeostasis include the following:

- Two closely related hormones secreted by the thyroid gland, tetraiodothyronine (T_4) and triiodothyronine (T_3), increase the overall metabolic rate. Not only does this action influence the

rate at which cells use nutrient molecules and oxygen within the internal environment but it also produces heat, which helps maintain body temperature.

- The adrenal cortex secretes three classes of hormones. Aldosterone, the primary mineralocorticoid, is essential for Na^+ and K^+ balance. Because of the osmotic effect of Na^+ , Na^+ balance is critical to maintaining the proper ECF volume and arterial blood pressure. This action is essential for life. Without aldosterone's Na^+ - and H_2O -conserving effect, so much plasma volume would be lost in the urine that death would quickly ensue. Maintaining K^+ balance is essential for homeostasis because changes in extracellular K^+ profoundly impact neuromuscular excitability, leading to detrimental effects, such as compromising normal heart function. Cortisol, the primary glucocorticoid secreted by the adrenal cortex, increases the plasma concentrations of glucose, fatty acids, and amino acids above normal. Although these actions destabilize the concentrations of these molecules in the internal environment, they indirectly contribute to homeostasis by making the molecules readily available as energy sources or building blocks for tissue repair to help the body adapt to stressful situations.
- The sex hormones secreted by the adrenal cortex do not contribute to homeostasis.
- The major hormone secreted by the adrenal medulla, epinephrine, generally reinforces activities of the sympathetic nervous system. It contributes to homeostasis directly by its role in blood pressure regulation. Epinephrine also contributes to homeostasis indirectly by helping prepare the body for peak physical responsiveness in fight-or-flight situations. This includes increasing the plasma concentrations of glucose and fatty acids above normal, thereby providing additional energy sources for increased physical activity.
- The two major hormones secreted by the endocrine pancreas—insulin and glucagon—are important in shifting metabolic pathways between the absorptive and postabsorptive states, which maintains the appropriate plasma levels of nutrient molecules.
- Parathyroid hormone from the parathyroid glands is critical to maintaining plasma concentration of Ca^{2+} . PTH is essential for life because of the effect of Ca^{2+} on neuromuscular excitability. In the absence of PTH, death rapidly occurs from asphyxiation caused by pronounced spasms of the respiratory muscles.

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-41)

6

- The response to thyroid hormone is detectable within a few minutes after its secretion. (*True or false?*)
- Male sex hormones are produced in both males and females by the adrenal cortex. (*True or false?*)
- Adrenal androgen hypersecretion is usually due to a deficit of an enzyme crucial to cortisol synthesis. (*True or false?*)
- Excess glucose and amino acids as well as fatty acids can be stored as triglycerides. (*True or false?*)
- Insulin is the only hormone that can lower blood glucose levels. (*True or false?*)
- The most life-threatening consequence of hypocalcaemia is reduced blood clotting. (*True or false?*)
- All ingested Ca^{2+} is indiscriminately absorbed in the intestine. (*True or false?*)
- The $Ca_3(PO_4)_2$ bone crystals form a labile pool from which Ca^{2+} can rapidly be extracted under the influence of PTH. (*True or false?*)
- The lumen of the thyroid follicle is filled with _____, the chief constituent of which is a large protein molecule known as _____.
- The common large precursor molecule that yields ACTH, MSH, and β -endorphin is known as _____.
- _____ is the conversion of glucose into glycogen.
 _____ is the conversion of glycogen into glucose.
 _____ is the conversion of amino acids into glucose.
- The three major tissues that are not dependent on insulin for their glucose uptake are _____, _____, and _____.
- The three compartments with which ECF Ca^{2+} is exchanged are _____, _____, and _____.
- Which hormone does NOT exert a direct metabolic effect?
 - epinephrine
 - growth hormone
 - aldosterone
 - cortisol
 - thyroid hormone
- Which of the following are characteristic of the postabsorptive state? (Indicate all correct answers.)
 - glycogenolysis
 - gluconeogenesis
 - lipolysis

- glycogenesis
- protein synthesis
- triglyceride synthesis
- protein degradation
- increased insulin secretion
- increased glucagon secretion
- glucose sparing

- Indicate the primary circulating form and storage form of each of the three classes of organic nutrients:

	Primary Circulating Form	Primary Storage Form
Carbohydrate	1. _____	2. _____
Fat	3. _____	4. _____
Protein	5. _____	6. _____

Written Questions

- Describe the steps of thyroid hormone synthesis.
- What are the effects of T_3 and T_4 ? Which is the more potent form? What is the source of most circulating T_3 ?
- Describe the regulation of thyroid hormone.
- Discuss the causes and symptoms of both hypothyroidism and hyperthyroidism. For each cause, indicate whether or not a goitre occurs, and explain why.
- What hormones are secreted by the adrenal cortex? What are the functions and control of each of these hormones?
- Discuss the causes and symptoms of each type of adrenocortical dysfunction.
- What is the relationship of the adrenal medulla to the sympathetic nervous system? What are the functions of epinephrine? How is epinephrine release controlled?
- Define *stress*. Describe the neural and hormonal responses to a stressor.
- Define *fuel metabolism*, *anabolism*, and *catabolism*.
- Distinguish between the absorptive and postabsorptive states with regard to the handling of nutrient molecules.
- Name the two major cell types of the islets of Langerhans, and indicate the hormonal product of each.
- Compare the functions and control of insulin secretion with those of glucagon secretion.

13. What are the consequences of diabetes mellitus? Distinguish between type 1 and type 2 diabetes mellitus.
14. Why must plasma Ca^{2+} be closely regulated?
15. Explain how osteoblasts influence osteoclast function.
16. Discuss the contributions of parathyroid hormone, calcitonin, and vitamin D to Ca^{2+} metabolism. Describe the source and control of each of these hormones.
17. Discuss the major disorders in Ca^{2+} metabolism.

POINTS TO PONDER

(Explanations in Appendix E, p. A-41)

1. Iodine is naturally present in salt water and is abundant in soil along coastal regions. Fish and shellfish living in the ocean and plants grown in coastal soil take up iodine from their environment. Fresh water does not contain iodine, and the soil becomes more iron-poor the farther inland it is. Knowing this, explain why the midwestern United States was once known as an *endemic goitre belt*. Why is this region no longer an endemic goitre belt even though the soil is still iodine poor?
2. Why do doctors recommend that people who are allergic to bee stings, and thus at risk for anaphylactic shock, carry a vial of epinephrine for immediate injection in case of a sting?
3. Why would an infection tend to raise the blood glucose level of a diabetic individual?
4. Tapping the facial nerve at the angle of the jaw in a patient with moderate hyposecretion of a particular hormone

elicits a characteristic grimace on that side of the face. What endocrine abnormality could give rise to this so-called *Chvostek's sign*?

5. Soon after a technique to measure plasma Ca^{2+} levels was developed in the 1920s, physicians observed that hypercalcaemia accompanied a broad range of cancers. Early researchers proposed that malignancy-associated hypercalcaemia arose from metastatic tumour cells that invaded and destroyed bone, releasing Ca^{2+} into the blood. This conceptual framework was overturned when physicians noted that hypercalcaemia often appeared in the absence of bone lesions. Furthermore, cancer patients often manifested hypophosphataemia in addition to hypercalcaemia. This finding led investigators to suspect that the tumours might be producing a PTH-like substance. Explain how they reached this conclusion. In 1987, this substance was identified and named *parathyroid hormone-related peptide (PTHrP)*, which binds to and activates PTH receptors.

6

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-42)

Najma G. sought medical attention after her menstrual periods ceased and she started growing excessive facial hair. Also, she had been thirstier than usual and urinated more frequently. A clinical evaluation revealed that Najma was

hyperglycaemic. Her physician told her that she had an endocrine disorder dubbed “diabetes of bearded ladies.” Based on her symptoms and your knowledge of the endocrine system, what underlying defect do you think is responsible for Najma’s condition?

Muscle Physiology

Body systems maintain homeostasis

Anatomical study *De Humani Corporis Fabrica*

Cells make up body systems

Homeostasis

Skeletal muscles contribute to homeostasis by playing a major role in the procurement of food, breathing, heat generation for maintenance of body temperature, and movement away from harm.

Homeostasis is essential for survival of cells

Jubal Harshaw/shutterstock.com

Striated (voluntary) muscle

Muscles are the contraction specialists of the body. Skeletal muscles attach to the skeleton. Contraction of skeletal muscles moves the bones to which they are attached, allowing the body to perform a variety of motor activities and all the movement necessary to sustain life. Skeletal muscles that support homeostasis include those important in chewing, swallowing, and breathing. As well, heat-generating muscle contractions are important in regulating body temperature. Skeletal muscles are further used to move the body away from harm (e.g., removing your hand from a hot stove). Skeletal

muscle contractions are also important for nonhomeostatic activities, such as dancing, operating a computer, or reading a book. Smooth muscle is found in the walls of hollow organs and tubes. Controlled contraction of smooth muscle, although involuntary, regulates movement of blood through blood vessels, food through the digestive tract, air through respiratory airways, and urine through the exterior. Cardiac muscle is found only in the walls of the heart, whose contractions pump life-sustaining blood throughout the body for an entire lifetime (based on 72 beats per minute to the age of 80 years, that is 3 027 456 000 beats!).

Clinical Connections

David is a 50-year-old male. Recently, his spouse has been trying to get him to be more active so they can exercise together. However, David finds that he cannot exercise for very long. This isn't new to him; even as a young child in school he couldn't keep up with his classmates in sports, and until recently he was content with an inactive life. Now that he is being encouraged to become active, however, this inability to exercise is becoming a concern to him. Whenever he does exercise, his legs rapidly tire and feel stiff, as if his muscles were locking on him. These symptoms go away after a period of rest, and he can continue to exercise again. Interestingly, he has greater endurance if he has recently eaten a meal.

A physical exam revealed only a generalized muscle weakness, but upon further questioning about his symptoms, David said he has on occasion noticed that his urine is darker after he has been active. Additional tests found that his creatine kinase levels were elevated, and a muscle biopsy showed excessive deposits of glycogen in his muscles. After an enzyme activity test demonstrated the absence of myophosphorylase, the doctor made a diagnosis of McArdle's disease.

7.1 | Introduction

By moving specialized intracellular components, muscle cells can develop tension and shorten—that is, contract. Recall that the three types of **muscle** are *skeletal muscle*, *cardiac muscle*, and *smooth muscle* (p. 6). Through their highly developed ability to contract, groups of muscle cells working together within a muscle can produce movement

and do work. Controlled contraction of muscles allows (1) purposeful movement of the whole body or parts of the body (such as walking or waving your hand), (2) manipulation of external objects (such as driving a car or moving a piece of furniture), (3) propulsion of contents through various hollow internal organs (such as circulation of blood or movement of a meal through the digestive tract), and (4) emptying the contents of certain organs to the external environment (such as urination or giving birth).

Muscle comprises the largest group of tissues in the body, accounting for approximately half of the body's weight. Skeletal muscle alone makes up about 40 percent of body weight in men and 32 percent in women. Smooth and cardiac muscle make up another 10 percent of the total weight. Although the three muscle types are structurally and functionally distinct, they can be classified in two different ways according to their common characteristics (► Figure 7-1). First, muscles are categorized as *striated* (skeletal and cardiac muscle) or *unstriated* (smooth muscle), depending on whether alternating dark and light bands—called striations (stripes)—can be seen when the muscle is viewed under a light microscope. Second, muscles are categorized as *voluntary* (skeletal muscle) or *involuntary* (cardiac and smooth muscle), depending, respectively, on whether they are innervated by the somatic nervous system and are subject to voluntary control, or are innervated by the autonomic nervous system and are not subject to voluntary control. Although skeletal muscle is categorized as voluntary, because it can be consciously controlled, much of the skeletal muscle activity is also subject to subconscious, involuntary regulation, such as that related to posture, balance, and stereotypical movements like walking.

Most of this chapter is a detailed examination of the most abundant and best understood muscle, **skeletal muscle**. Skeletal muscles make up the muscular system. We begin with a discussion of skeletal muscle structure, and then examine how it works at the molecular level, the cell level, and in the whole muscle. The chapter also includes a discussion of the unique properties of smooth and cardiac muscle in comparison with skeletal muscle. Smooth muscle appears throughout the body systems as components of hollow organs and tubes. Cardiac muscle is found only in the heart.

► FIGURE 7-1 Categorization of muscle

7.2 | Structure of Skeletal Muscle

A single skeletal muscle cell, known as a muscle fibre, is relatively large, elongated, and cylinder shaped, measuring 10–100 μm (micrometre) in diameter and up to 750 000 μm , or 0.76 m, in length (1 μm = 1 millionth of a metre). In a person who is about 1.8 m tall, the longest muscle fibre in the body is about 50 cm. A skeletal muscle consists of a number of muscle fibres lying parallel to one another and bundled together by connective tissue (► Figure 7-2a). The fibres usually extend the entire length of the muscle. During embryonic development, the huge skeletal muscle fibres are formed by the fusion of many smaller cells called myoblasts (*myo* means “muscle”; *blast* means “former”); thus, a striking feature of myoblasts is the presence of multiple nuclei in a single muscle cell. Another feature is the abundance of mitochondria, the energy-generating organelles, as would be expected with the high energy demands of a tissue as active as skeletal muscle.

Skeletal muscle fibres

The predominant structural feature of a skeletal muscle fibre is the numerous **myofibrils**. These specialized contractile elements—which constitute 80 percent of the volume of the muscle fibre—are cylindrical intracellular structures, 1 μm in diameter, that extend the entire length of the muscle fibre (► Figure 7-2b). Each myofibril consists of a regular arrangement of highly organized cytoskeletal elements: the thick and the thin filaments (► Figure 7-2c). The **thick filaments**, which are 12–18 nm (nanometre) in diameter and 1.6 μm in length, are special assemblies of the protein *myosin*. The **thin filaments**, which are 5–8 nm in diameter and 1.0 μm long, are made up primarily of the protein *actin* (► Figure 7-2d). The levels of organization in a skeletal muscle can be summarized as follows:

Each muscle is covered by a dense connective tissue made primarily of collagen and to a lesser extent elastin. The connective tissue is very important in that it provides structure to the muscle and allows the transfer of force to the bone. This provides tension for stabilization and/or movement. The three anatomic connective tissues are **epimysium**, which covers the whole muscle; **perimysium**, which divides the muscle fibres into bundles or fascicles; and **endomysium**, the innermost connective tissue, which covers each muscle fibre or cell. It is the contractile components of the skeletal muscle fibres that transfer force to the connective tissue sheaths, then to the **tendon**, and finally to the bone, thereby providing the human body with the ability to stabilize body segments, manipulate objects, and locomote.

FIGURE 7-2 Levels of organization in a skeletal muscle

A AND I BANDS

Viewed with an electron microscope, a myofibril displays alternating dark bands (the *A bands*) and light bands (the *I bands*) (► Figure 7-3a). The bands of all the myofibrils lined up parallel to one another collectively produce the striated or striped appearance of a skeletal muscle fibre visible under a light microscope (► Figure 7-3b). Alternate stacked sets of thick and thin filaments that slightly overlap one another are responsible for the A and I bands (► Figure 7-2c).

An **A band** is made up of a stacked set of thick filaments along with the portions of the thin filaments that overlap on both ends of the thick filaments. The thick filaments lie only within the A band and extend its entire width; that is, the two ends of the thick filaments within a stack define the outer limits of a given A band. The lighter area within the middle of the A band, where the thin filaments do not reach, is the **H zone**. Only the central portions of the thick filaments are found in this region. Within each stack, a system of supporting proteins holds the thick filaments together vertically. These proteins can be seen as the **M line**, which extends vertically down the middle of the A band within the centre of the H zone.

► **FIGURE 7-3** Microscope view of skeletal muscle components. (a) Electron microscope view of a myofibril. Note the A and I bands. (b) Low-power light-microscope view of skeletal muscle fibres. Note the striated appearance.

Mackenzie of the Anatomy and Cell Biology Program in the Department of Biomedical and Molecular Sciences, Faculty of Health Sciences at Queen's University, Kingston, Ontario, Canada.

An **I band** consists of the remaining portion of the thin filaments that do not project into the A band. Visible in the middle of each I band is a dense, vertical **Z line**. The area between two Z lines is called a **sarcomere**, which is the functional unit of skeletal muscle. A **functional unit** of any organ is the smallest component that can perform all the functions of that organ. The sarcomere is the smallest component of a muscle fibre that can contract. The Z line (also known as Z discs) is a flat, cytoskeletal disc that connects the thin filaments of two adjoining sarcomeres. Each relaxed sarcomere is about 2.5 µm in width and consists of one whole A band and half of each of the two I bands located on either side. An I band contains only thin filaments from two adjacent sarcomeres, but not the entire length of these filaments. During growth, a muscle increases in length by adding new sarcomeres on the ends of the myofibrils, not by increasing the size of each sarcomere. As well, an increase in flexibility through the use of a regular stretching program is brought about by the addition of new sarcomeres.

Shown in Figure 7-2, single strands of a giant, highly elastic protein known as **titin** extend in both directions from the M line along the length of the thick filament to the Z lines at opposite ends of the sarcomere. Titin is the largest protein in the body, made up of nearly 30 000 amino acids. It serves two important roles: (1) along with the M-line proteins, titin helps stabilize the position of the thick filaments in relation to the thin filaments; and (2) by acting like a spring, it greatly augments a muscle's elasticity. That is, titin helps a muscle stretched by an external force to passively recoil or spring back to its resting length when the stretching force is removed, much like a stretched spring.

CROSS BRIDGES

With an electron microscope, fine **cross bridges** (**myosin heads**) can be seen extending from each thick filament toward the surrounding thin filaments in the areas where the thick and thin filaments overlap (see ► Figure 7-2c). Three-dimensionally, the thin filaments are arranged hexagonally around the thick filaments. Cross bridges project from each thick filament in all six directions toward the surrounding thin filaments. Each thin filament, in turn, is surrounded by three thick filaments. To give you an idea of the magnitude of these filaments, a single muscle fibre may contain an estimated 16 billion thick and 32 billion thin filaments, all arranged in a very precise pattern within the myofibrils.

Myosin

Each thick filament has several hundred **myosin** molecules packed together in a specific arrangement. Myosin is considered a motor protein and is responsible for action-based motility. A myosin molecule is a protein consisting of two identical subunits, each shaped somewhat like a golf club (► Figure 7-4a). The protein's tail ends are intertwined around each other like golf-club shafts twisted together, with the two globular heads projecting out at one end. The two halves of each thick filament are mirror images made up of myosin molecules lying lengthwise

► **FIGURE 7-4** Structure of myosin molecules and their organization within a thick filament.

(a) Each myosin molecule consists of two identical, golf-club-shaped subunits with their tails intertwined and their globular heads, each of which contains an actin-binding site and a myosin ATPase site, projecting out at one end. (b) A thick filament is made up of myosin molecules lying lengthwise parallel to one another. Half are oriented in one direction and half in the opposite direction. The globular heads, which protrude at regular intervals along the thick filament, form the cross bridges.

in a regular, staggered array, with their tails oriented toward the centre of the filament and their globular heads protruding outward at regular intervals (► Figure 7-4b). These heads form the cross bridges between the thick and thin filaments. Each cross bridge has two important sites crucial to the contractile process: (1) an actin-binding site and (2) a myosin ATPase (ATP-splitting) site. It is the rate of ATPase activity on the head of the myosin that provides a method of muscle fibre typing (p. 319).

► **FIGURE 7-5** Composition of a thin filament. The main structural component of a thin filament is two chains of spherical actin molecules that are twisted together. Troponin molecules (which consist of three small, spherical subunits) and threadlike tropomyosin molecules are arranged to form a ribbon that lies alongside the groove of the actin helix and physically covers the binding sites on actin molecules for attachment with myosin cross bridges. (The thin filaments shown here are not drawn in proportion to the thick filaments in Figure 7-4. Thick filaments are two to three times larger in diameter than the thin filaments.)

Actin, tropomyosin, and troponin

Thin filaments consist of three proteins: *actin*, *tropomyosin*, and *troponin* (► Figure 7-5). **Actin** molecules, the primary structural proteins of the thin filament, are spherical. The backbone of a thin filament is formed by actin molecules joined into two strands and twisted together, like two intertwined strings of pearls. Each actin molecule has a special binding site for attachment with a myosin cross bridge. The binding of myosin and actin molecules at the cross bridges results in the energy-consuming contraction of the muscle fibre; this mechanism is described in Section 7.3. Accordingly, myosin and actin are often called **contractile proteins**, even though, as you will see, neither myosin nor actin actually contracts. Myosin and actin are not unique to muscle cells, but these proteins are more abundant and more highly organized in muscle cells. It is important to note that there are numerous actin-binding proteins (ABPs), an example of which is **nebulin**, but this class of proteins will not be discussed in detail.

In a relaxed muscle fibre, contraction does not take place; actin cannot bind with cross bridges, because of the way the two other types of protein—tropomyosin and troponin—are positioned within the thin filament. **Tropomyosin** molecules are threadlike proteins that lie end to end alongside the groove of the actin

► FIGURE 7-6 Role of calcium in turning on cross bridges

spiral. In this position, tropomyosin covers the actin sites that bind with the cross bridges, blocking the interaction that leads to muscle contraction. The other thin filament component, **troponin**, is a protein complex made of three polypeptide units: one binds to tropomyosin, one binds to actin, and a third can bind with calcium Ca^{2+} .

When troponin is not bound to Ca^{2+} , this protein stabilizes tropomyosin in its blocking position over actin's cross-bridge binding sites (► Figure 7-6a). When Ca^{2+} binds to troponin, the shape of this protein is changed in such a way that tropomyosin slips away from its blocking position (► Figure 7-6b). With tropomyosin out of the way, actin and myosin can bind and interact at the cross bridges, resulting in muscle contraction. Tropomyosin and troponin are often called **regulatory proteins** because of their role in covering (preventing contraction) or exposing (permitting contraction) the binding sites for cross-bridge interaction between actin and myosin.

Check Your Understanding 7.1

1. Compare the relationship of myofibrils and a muscle fibre with the relationship between muscle fibres and a whole muscle.
2. Describe the relationship between actin, tropomyosin, and troponin in a relaxed muscle fibre.

7.3 Molecular Basis of Skeletal Muscle Contraction

Several important links in the contractile process remain to be discussed. How does cross-bridge interaction between actin and myosin bring about muscle contraction? How does a muscle

action potential trigger this contractile process? What is the source of the calcium that physically repositions troponin and tropomyosin to permit cross-bridge binding? We turn our attention to these topics in this section.

Cross bridges

Cross-bridge interaction between actin and myosin brings about muscle contraction by means of the sliding filament mechanism.

SLIDING FILAMENT MECHANISM

During contraction, the thin filaments on each side of a sarcomere slide inward over the stationary thick filaments toward the A band's centre (► Figure 7-7). As they slide inward, the thin filaments pull the Z lines to which they are attached closer together, so the sarcomere shortens. As all the sarcomeres throughout the muscle fibre's length shorten simultaneously, the entire fibre shortens. When a muscle fibre contracts, moving the Z lines closer together, the muscle fibre and thus the whole muscle shortens. This is called a *concentric contraction* (p. 315). This is the **sliding filament mechanism** of muscle contraction. The H zone, in the centre of the A band where the thin filaments do not reach, becomes smaller as the thin filaments approach each other when they slide more deeply inward. The I band, which consists of the portions of the thin filaments that do not overlap with the thick filaments, narrows as the thin filaments further overlap the thick filaments during their inward slide. The thin filaments themselves do not change length during muscle fibre shortening. The width of the A band remains unchanged during contraction, because its width is determined by the length of the thick filaments, and the thick filaments do not change length during the shortening process. Note that neither the thick nor the thin filaments decrease in length to shorten the sarcomere. Instead, contraction is accomplished by the thin filaments from the opposite sides of each sarcomere sliding closer together between the thick filaments.

POWER STROKE

Cross-bridge activity pulls the thin filaments inward relative to the stationary thick filaments. During contraction—with the tropomyosin and troponin “chaperones” pulled out of the way by calcium—the myosin cross bridges from a thick filament can bind with the actin molecules in the surrounding thin filaments. Let's concentrate on a single cross-bridge interaction (► Figure 7-8a). The two myosin heads of each myosin molecule act independently, with only one head attaching to actin at a given time. When myosin and actin make contact at a cross bridge, the bridge changes shape, bending inward as if it were on a hinge, “stroking” toward the centre of the sarcomere, like the stroking of a boat oar. This so-called **power stroke** of a cross

► **FIGURE 7-7** Changes in banding pattern during shortening. During muscle contraction, each sarcomere shortens as the thin filaments slide closer together between the thick filaments so that the Z lines are pulled closer together. The width of the A bands does not change as a muscle fibre shortens, but the I bands and H zones become shorter.

bridge pulls inward the thin filament to which it is attached. A single power stroke pulls the thin filament inward only a small percentage of the total shortening distance. Repeated cycles of cross-bridge binding and bending complete the shortening.

At the end of one cross-bridge cycle, the link between the myosin cross bridge and actin molecule breaks. The cross bridge returns to its original shape and binds to the next actin molecule behind its previous actin partner. The cross bridge bends once again to pull the thin filament in farther, then detaches and repeats the cycle. Repeated cycles of cross-bridge power strokes successively pull in the thin filaments, much like pulling in a rope hand over hand.

Because of the way myosin molecules are oriented within a thick filament (► Figure 7-8b), all the cross bridges stroke toward the centre of the sarcomere so that all six of the surrounding thin filaments on each end of the sarcomere are pulled inward simultaneously (► Figure 7-8c). The cross bridges aligned with given thin filaments do not stroke all in unison, however. At any time during contraction, part of the cross bridges are attached to the thin filaments and are stroking, while others are returning to their original conformation in preparation for binding with another actin molecule. Thus, some cross bridges are “holding on” to the thin filaments, whereas others “let go” to bind with new actin. Were it not for this asynchronous cycling of the cross bridges, the thin filaments would slip back toward their resting position between strokes.

How does muscle excitation switch on this cross-bridge cycling? The term **excitation-contraction coupling** refers to the series of events linking muscle excitation (the presence of an

► **FIGURE 7-8 Cross-bridge activity.** (a) During each cross-bridge cycle, the cross bridge binds with an actin molecule, bends to pull the thin filament inward during the power stroke, then detaches and returns to its resting conformation, ready to repeat the cycle. (b) The power strokes of all cross bridges extending from a thick filament are directed toward the centre of the thick filament. (c) Each thick filament is surrounded on each end by six thin filaments, all of which are pulled inward simultaneously through cross-bridge cycling during muscle contraction.

action potential in a muscle fibre) to muscle contraction (cross-bridge activity that causes the thin filaments to slide closer together to produce sarcomere shortening). We now turn our attention to excitation–contraction coupling.

Excitation–contraction coupling

Skeletal muscles are stimulated to contract by release of acetylcholine (ACh) at neuromuscular junctions between motor-neuron terminals and muscle fibres. Recall that binding of ACh with the motor end plate of a muscle fibre brings about permeability changes in the muscle fibre, resulting in an action potential that is conducted over the entire surface of the muscle cell membrane (p. 197). Two membranous structures within the muscle fibre play an important role in linking this excitation to contraction—*transverse tubules* and the *sarcoplasmic reticulum* (SR). Let's examine the structure and function of each.

SPREAD OF THE ACTION POTENTIAL DOWN THE T TUBULES

At each junction of an A band and I band, the surface membrane dips into the muscle fibre to form a **transverse tubule** (T tubule), which runs perpendicularly from the surface of the muscle cell membrane into the central portions of the muscle fibre (► Figure 7-9). Because the T tubule membrane is continuous with the surface membrane, an action potential on the surface membrane also spreads down into the T tubule, rapidly transmitting the surface electrical activity into the central portions of the fibre. The presence of a local action potential in the T tubules induces permeability changes in a separate membranous network within the muscle fibre—the sarcoplasmic reticulum.

RELEASE OF CALCIUM FROM THE SARCOPLASMIC RETICULUM

The **sarcoplasmic reticulum** (SR) is a modified endoplasmic reticulum that consists of a fine network of interconnected compartments surrounding each myofibril like a mesh sleeve (► Figure 7-9). This membranous network encircles the myofibril throughout its length but is not continuous. Separate segments of SR are wrapped around each A band and each I band. The ends of each segment expand to form saclike regions—the **lateral sacs** (alternatively known as **terminal cisternae**)—which are separated from the adjacent T tubules by a slight gap (► Figure 7-9 and ► Figure 7-10). The SR's lateral sacs store calcium. Spread of an action potential down a T tubule triggers release of calcium from the SR into the cytosol.

How is a change in T tubule potential linked with the release of calcium from the lateral sacs? An orderly arrangement of **foot proteins** extends from the SR and spans the gap between the lateral sac and T tubule. Each foot protein contains four subunits arranged in a specific pattern (► Figure 7-10a). These foot proteins not only bridge the gap but also serve as Ca^{2+} -release channels. These foot-protein Ca^{2+} channels are also known as **ryanodine receptors** because they are locked in the open position by the plant chemical ryanodine.

Half of the SR's foot proteins are “zipped together” with complementary receptors on the T tubule side of the junction. These

FIGURE 7-9 The T tubules and sarcoplasmic reticulum in relationship to the myofibrils. The transverse (T) tubules are membranous, perpendicular extensions of the surface membrane that dip deep into the muscle fibre at the junctions between the A and I bands of the myofibrils. The SR is a fine, membranous network that runs longitudinally and surrounds each myofibril, with separate segments encircling each A band and I band. The ends of each segment are expanded to form lateral sacs that lie next to the adjacent T tubules.

T tubule receptors, which are made up of four subunits in exactly the same pattern as the foot proteins, are located like mirror images in contact with every other foot protein protruding from the SR (Figure 7-10b and 7-10c). These T tubule receptors are known as **dihydropyridine receptors** because they are blocked by the drug dihydropyridine. These dihydropyridine receptors are voltage-gated sensors. When an action potential is propagated down the T tubule, the local depolarization activates the voltage-gated dihydropyridine receptors. The activated T tubule receptors, in turn, trigger the opening of the directly abutting Ca^{2+} -release channels (alias ryanodine receptors, alias foot proteins) in the adjacent lateral sacs of the SR. Opening of the half of the Ca^{2+} -release channels in direct contact with the dihydropyridine receptors triggers the opening of the other half of the Ca^{2+} -release channels that are not directly associated with the T tubule receptors.

FIGURE 7-10 Relationship between a T tubule and the adjacent lateral sacs of the sarcoplasmic reticulum

Calcium is released into the cytosol from the lateral sacs through all these open Ca^{2+} -release channels. By slightly repositioning the troponin and tropomyosin molecules, this released calcium exposes the binding sites on the actin molecules so they can link with the myosin cross bridges at their complementary binding sites (► Figure 7-11).

ATP-POWERED CROSS-BRIDGE CYCLING

Recall that a myosin cross bridge has two special sites—an actin-binding site and an ATPase site. The latter is an enzymatic site that can bind the energy carrier *adenosine triphosphate* (ATP) and split it into *adenosine diphosphate* (ADP) and *inorganic phosphate* (P_i), yielding energy in the process. The breakdown of ATP occurs on the myosin cross bridge before the bridge ever links with an actin molecule (► Figure 7-12, step 1). The ADP and P_i remain tightly bound to the myosin, and the generated energy is stored within the cross bridge to produce a high-energy form of myosin. To use an analogy, the cross bridge is cocked like a gun, ready to be fired when the trigger is pulled. When the muscle fibre is

excited, Ca^{2+} pulls the troponin–tropomyosin complex out of its blocking position so that the energized (cocked) myosin cross bridge can bind with an actin molecule (step 2a). This contact between myosin and actin “pulls the trigger,” causing the cross-bridge bending that produces the power stroke (step 3). Researchers have not found the mechanism by which the chemical energy released from ATP is stored within the myosin cross bridge and then translated into the mechanical energy of the power stroke. Inorganic phosphate is released from the cross bridge during the power stroke. After the power stroke is complete, ADP is released.

When the muscle is not excited and Ca^{2+} is not released, troponin and tropomyosin remain in their blocking position so that actin and the myosin cross bridges do not bind and no power stroking takes place (step 2b).

When P_i and ADP are released from myosin following contact with actin and the subsequent power stroke, the myosin ATPase site is free for attachment of another ATP molecule. The actin and myosin remain linked at the cross bridge until a fresh

► **FIGURE 7-11** Calcium release in excitation–contraction coupling. Steps 1 through 5 show the events that couple neurotransmitter release and subsequent electrical excitation of the muscle cell with muscle contraction. Steps 6 and 7 show events associated with muscle relaxation.

molecule of ATP attaches to myosin at the end of the power stroke. Attachment of the new ATP molecule permits detachment of the cross bridge, which returns to its unbent form, ready to start another cycle (step **4a**). The newly attached ATP is then

split by myosin ATPase, energizing the myosin cross bridge once again (step **1**). On binding with another actin molecule, the energized cross bridge again bends, and so on, successively pulling the thin filament inward to accomplish contraction.

FIGURE 7-12 Cross-bridge cycle

Why It Matters Rigor Mortis

Note that fresh ATP must attach to myosin to permit the cross-bridge link between myosin and actin to break at the end of a cycle, even though the ATP is not split during this dissociation process. The need for ATP in separating myosin and actin is amply shown in **rigor mortis**. This “stiffness of death” is a generalized locking in place of the skeletal muscles that begins 3 to 4 hours after death and completes in about 12 hours. Following death, the cytosolic concentration of calcium begins to rise, most likely because the inactive muscle cell membrane cannot keep out extracellular Ca^{2+} and perhaps also

because Ca^{2+} leaks out of the lateral sacs. This Ca^{2+} moves the regulatory proteins aside, letting actin bind with the myosin cross bridges, which were already charged with ATP before death. Dead cells cannot produce any more ATP, so actin and myosin, once bound, cannot detach, because they lack fresh ATP. The thick and thin filaments thus stay linked by the immobilized cross bridges, leaving dead muscles stiff (Figure 7-12, step **4b**). During the next several days, rigor mortis gradually subsides as the proteins involved in the rigor complex begin to degrade.

RELAXATION

How is **relaxation** normally accomplished in a living muscle? Just as an action potential in a muscle fibre turns on the contractile process by triggering the release of Ca^{2+} from lateral sacs into the cytosol, the contractile process is turned off when Ca^{2+} is returned to the lateral sacs when local electrical activity stops. The SR has an energy-consuming carrier, a Ca^{2+} -ATPase pump, which actively transports Ca^{2+} from the cytosol and concentrates it in the lateral sacs. When acetylcholinesterase (AChE) removes ACh from the neuromuscular junction, the muscle fibre action potential stops. When a local action potential is no longer in the T tubules to trigger the release of Ca^{2+} , the ongoing activity of the SR's Ca^{2+} pump returns released Ca^{2+} back into its lateral sacs. Removing cytosolic Ca^{2+} lets the troponin-tropomyosin complex slip back into its blocking position, so actin and myosin can no longer bind at the cross bridges. The thin filaments, freed from cycles of cross-bridge attachment and pulling, return passively to their resting position. The muscle fibre has relaxed.

We are now going to compare the duration of contractile activity with the duration of excitation.

Clinical Connections

McArdle's disease is a characterized by the absence of the enzyme phosphorylase, a key enzyme required in breaking down glycogen to release glucose for ATP production. Without this enzyme, glycogen accumulates in muscles, and alternate fuel sources are required to maintain muscle activity. When David starts to exercise, he rapidly depletes his ATP pools, and he feels muscle weakness. The sensation of his legs locking is due to the lack of ATP and is the equivalent of a living rigor mortis. After a rest, his body has mobilized fatty acids and glucose that are then used by the muscle to produce ATP. (Recall from Chapter 2 how fatty acids and glucose are used to make ATP.) Then he can exercise again.

Contractile activity

A single action potential in a skeletal muscle fibre lasts only 1–2 msec. The onset of the resulting contractile response lags behind the action potential because the entire excitation-contraction coupling must occur before cross-bridge activity begins, resulting in shortening of the sarcomere. In fact, the action potential is completed before the contractile apparatus even becomes operational. This time delay, about 0.5 msec between stimulation and the onset of contraction, is called the **latent period** (► Figure 7-13).

Time is also required for generating tension within the muscle fibre, produced by the sliding interactions between the thick and thin filaments through cross-bridge activity. The time from the onset of contraction until peak tension develops—**contraction time**—averages about 40–120 msec. This time varies depending on the type of muscle fibre. Fast-twitch (FT)

muscle fibres reach peak tension faster than slow-twitch (ST) muscle fibres. This difference results from the variation in ATPase activity associated with the myosin heavy chain (for more on fibre types, see the section Muscle Fibre Types within a Single Motor Unit). Here are some examples of variation in contraction time among human skeletal muscles (approximate mean values for % ST and time in msec): frontalis oculi (15% ST), 45 msec; vastus lateralis (45% ST) and biceps brachii (40% ST), 65 msec; lateral gastrocnemius (50% ST) and soleus (80% ST), 120 msec.

The contractile response does not end until all the Ca^{2+} released in response to the action potential is removed. The time from peak tension until relaxation is complete—the **relaxation time**—usually lasts another 50–200 msec. And again, the time required for the muscle fibre to relax is based on the fibre type, with FT relaxing quicker than ST. Slow-twitch fibres have a lower density of SR and slower Ca^{2+} re-uptake. Remember that muscle relaxation, following a single twitch or a titanic contraction, is dictated by the efficiency of the three processes that remove Ca^{2+} : (1) dissociation of Ca^{2+} from troponin, (2) translocation of Ca^{2+} to near the site of entry into the SR, and (3) uptake of Ca^{2+} into the lateral sacs of the SR by the Ca^{2+} pump. Consequently, the entire contractile response to a single action potential may last up to 100 msec or more; this is much longer than the duration of the action potential that initiated it (100 msec

► **FIGURE 7-13** Relationship of an action potential to the resultant muscle twitch

2. Describe the role of the dihydropyridine and ryanodine receptors in the process of excitation–contraction coupling.
3. Diagram the cross-bridge cycle, and illustrate whether ATP, ADP, or ADP and P_i are bound to the myosin head during the various stages of the cycle.

compared with 1–2 msec). This fact is important in the body's ability to produce muscle contractions of variable strength, as you will soon discover in the next section, where we discuss skeletal muscle mechanics.

7.4 | Skeletal Muscle Mechanics

Thus far we have described the contractile response in a single muscle fibre. In the body, groups of muscle fibres are organized into whole muscles. We now turn our attention to the contraction of whole muscles and the factors that contribute to muscle tension.

Whole muscles

Each person has about 600 skeletal muscles, which range in size from the delicate external eye muscles that control eye movements and contain only a few hundred fibres, to the large, powerful leg muscles that contain several hundred thousand fibres.

Examples of the number of muscle fibres contained in other human muscles are provided in ■ Table 7-1.

Each muscle is sheathed by connective tissue that penetrates from the surface into the muscle to envelop each individual fibre and divide the muscle into columns or bundles. The connective tissue extends beyond the ends of the muscle to form tough, collagenous tendons that attach the muscle to bones. A tendon may be quite long, attaching to a bone some distance from the fleshy part of the muscle. For example, some of the muscles involved in finger movement are in the forearm, with long tendons extending down to attach to the bones of the fingers. (You can see these tendons move on the posterior aspect of your hand when you wiggle your fingers.) This arrangement permits greater dexterity; the fingers would be much thicker and more awkward if all the muscles used in finger movement were actually in the fingers.

Muscle contractions

A single action potential in a muscle fibre produces a brief, weak contraction called a **twitch**, which is too short and too weak to be useful and normally does not take place on its own. Muscle fibres are arranged into whole muscles, where they function cooperatively to produce contractions of variable grades of strength stronger than a twitch. In other words, you can vary the force you exert by the same muscle, depending on whether you are picking up a piece of paper, a book, or a 25 kg weight. Two primary factors can be adjusted to accomplish gradation of whole-muscle tension: (1) *the number of muscle fibres contracting within a muscle (i.e., motor unit recruitment)* and (2) *the firing frequency of each contracting fibre (i.e., frequency of stimulation)*.

It is worth noting that these two strategies for generating force, motor unit recruitment and frequency of stimulation, are not used equally by all muscles. Small, distal muscles (e.g., muscles of the hand) rely more on increasing the firing frequency to increase the force produced; whereas the larger, more proximal muscles rely more on motor unit recruitment. Increasing the firing frequency of the motor unit has been shown to amplify force by tenfold. Adding more motor units can be incredibly effective, as some motor units can produce 100 times more force than other motor units within the same whole muscle (e.g., quadriceps). One last comment before we examine these two force-generating strategies in more detail: it seems that when submaximal forces are required, motor unit recruitment is the more effective mechanism for increasing force, but as the muscles come closer to generating maximal force, the firing frequency becomes more important.

Motor unit recruitment

The greater is the number of fibres recruited to contract, the greater the total muscle tension. Therefore, larger muscles consisting of more muscle fibres obviously can generate more tension than can smaller muscles with fewer fibres.

Each whole muscle is innervated by a number of different motor neurons. When a motor neuron enters a muscle, it branches, and each axon terminal supplies a single muscle fibre (► Figure 7-14). One motor neuron innervates a number

FIGURE 7-14 Motor units in a skeletal muscle

of muscle fibres, but each muscle fibre is supplied by only one motor neuron. When a motor neuron is activated, all the muscle fibres it supplies are stimulated to contract simultaneously. This team of concurrently activated components—one motor neuron plus all the muscle fibres it innervates—is called a **motor unit**. The muscle fibres that compose a motor unit are dispersed throughout the whole muscle; thus, their simultaneous contraction results in an evenly distributed, although weak, contraction of the whole muscle (e.g., the biceps brachii). Each muscle consists of a number of intermingled motor units. For a weak contraction of the whole muscle, only one or a few of its motor units are activated. For stronger and stronger contractions, more and more motor units are recruited, or stimulated to contract. This phenomenon is known as **motor unit recruitment**.

The order of motor unit recruitment is based on the **size principle**: the larger the size of the motor unit, the harder it is to activate. Larger motor units are typically associated with larger motor neurons. In practical terms, it takes a larger voluntary effort, and thus a greater firing frequency, to recruit the larger motor units. As you add more weight to a barbell and lift it, with each addition of weight you will gradually recruit larger motor units to do the work. Therefore, the order of recruitment as it pertains to skeletal muscle fibre is as follows: slow-twitch → fast-twitch A → fast-twitch X. However, research has suggested that this order of recruitment may vary slightly depending on the motion at the joint. For example, the order of motor unit recruitment may change in the biceps brachii when the elbow flexes versus when it supinates. However, in most cases, the order of recruitment, smallest to largest, holds true.

How much stronger the contraction will be with the recruitment of each additional motor unit depends on the size of the motor units (i.e., the number of muscle fibres controlled by a single motor neuron). The number of muscle fibres per motor unit and the number of motor units per muscle vary widely, depending on the specific function of the muscle. For muscles that produce precise, delicate movements, such as external eye muscles and hand muscles, a single motor unit may contain as few as a dozen muscle fibres. Because so few muscle fibres are involved with each motor unit, recruitment of each additional

motor unit adds only a small increment to the whole muscle's strength of contraction. These small motor units allow very fine control over muscle tension. In contrast, in muscles designed for powerful, coarsely controlled movement, such as those of the legs, a single motor unit may contain 1500 to 2000 muscle fibres. Recruitment of each additional motor unit in these large muscles results in great incremental increases in whole-muscle tension. More powerful contractions occur at the expense of precisely controlled gradations. Thus, the number of muscle fibres participating in the whole muscle's total contractile effort depends on the number of motor units recruited and the number of muscle fibres per motor unit in that muscle.

To delay or prevent **fatigue** (the inability to maintain muscle tension at a specified level) during a sustained contraction involving only a portion of a muscle's motor units, as is necessary in muscles supporting the weight of the body against the force of gravity, **asynchronous recruitment of motor units** takes place. The body alternates motor unit activity, like shifts at a factory, to give motor units that have been active an opportunity to rest while others take over. Changing of the shifts is carefully coordinated, so the sustained contraction is smooth rather than jerky. Asynchronous motor unit recruitment is possible only for submaximal contractions, during which only some of the motor units must maintain the desired level of tension. During maximal contractions to move heavy loads, when all the muscle fibres must participate, it is impossible to alternate motor unit activity to prevent fatigue. This is one reason why you cannot support a heavy object as long as a light one.

Furthermore, the type of muscle fibre that is activated varies with the extent of gradation. Most muscles consist of a mixture of fibre types that differ metabolically, some being more resistant to fatigue than others. During weak or moderate endurance-type activities (aerobic exercise), the motor units most resistant to fatigue are recruited first (i.e., slow-twitch fibres). The last fibres to be called into play in the face of demands for further increases in tension are those that fatigue rapidly (fast-twitch A and then B). An individual can therefore engage in endurance activities for prolonged periods of time but can only briefly maintain bursts of all-out, powerful effort. Of course, even the muscle fibres most resistant to fatigue will eventually fatigue if required to maintain a certain level of sustained tension.

Frequency of stimulation

Whole-muscle tension depends not only on the number of muscle fibres contracting but also on the tension developed by each contracting fibre. Various factors influence the extent to which tension can be developed. These factors include the following:

1. Frequency of stimulation
2. Length of the fibre at the onset of contraction
3. Extent of fatigue
4. Thickness of the fibre

We will discuss each of these factors beginning with frequency of stimulation.

TWITCH SUMMATION AND TETANUS

Even though a single action potential (duration 1–2 msec) in a muscle fibre produces only a twitch, contractions with longer duration and greater tension can be achieved by repeated stimulation of the fibre. What happens when a second action potential occurs in a muscle fibre depends on the relaxation state of the muscle fibre. If the muscle fibre has completely relaxed (taking 80–200 msec) before the next action potential takes place, a second twitch of the same magnitude as the first occurs (▶ Figure 7-15a). The same excitation–contraction events take place each time, resulting in identical twitch responses. If, however, the muscle fibre is stimulated a second time before it has completely relaxed from the first twitch, a second action potential causes a second contractile response, which is added “piggybacked” on top of the first twitch (▶ Figure 7-15b). The two twitches from the two action potentials add together, or sum, to produce greater tension in the fibre than that produced by a single action potential. This **twitch summation** is similar to temporal summation of EPSPs at the postsynaptic neuron (p. 76).

Twitch summation is possible only because the duration of the action potential (1–2 msec) is much shorter than the duration of the resulting twitch (100 msec). Once an action potential has been initiated, a brief refractory period occurs during which another action potential cannot be initiated (p. 69). It is therefore impossible to achieve summation of action potentials. The membrane must return to resting potential and recover from its refractory period before another action

potential can occur. However, because the action potential and refractory period are over long before the resulting muscle twitch is completed, the muscle fibre may be restimulated while some contractile activity still exists, to produce summation of the mechanical response.

So how many action potentials are required to induce summation—that is, produce a useful muscle contraction? Again, this depends on the muscle fibre type, but the range of firing frequencies required to initiate a twitch summation for a sub-maximal force output is between 8 to 12 hertz (Hz), with a moderate contractile force requiring approximately 30 Hz. To put this into perspective, 1 Hz equals one stimulation per second, so 8 Hz equals eight stimulations (action potentials) per second.

If the muscle fibre is stimulated so rapidly that it does not have a chance to relax at all between stimuli, a smooth, sustained contraction of maximal strength known as **tetanus** occurs (▶ Figure 7-15c). A tetanic contraction is usually three to four times stronger than a single twitch. (Don’t confuse this normal physiological tetanus with the disease tetanus; see p. 82.) It is more difficult to determine the firing frequency necessary to produce a maximal force. The overlapping of the motor units within a whole muscle makes measurement of the firing frequency difficult. However, it is generally believed that a firing frequency of 60 Hz is sufficient to generate maximal force in a muscle (▶ Figure 7-16 shows a force–firing frequency curve for muscle), with approximately 100 Hz required for tetanus.

▶ FIGURE 7-15 Summation and tetanus

► **FIGURE 7-16 Force-firing frequency curve for human muscle.** As the firing frequency of the nerve increases, the force developed by the muscle increases, and at about 60 Hz no further increase in firing frequency will elicit a greater increase in force.

Twitch summation at the cellular level

What is the mechanism of twitch summation and tetanus at the cell level? The tension produced by a contracting muscle fibre increases as a result of greater cross-bridge cycling. As the frequency of action potentials increases, the resulting tension development increases until a maximum tetanic contraction is achieved. Enough calcium is released in response to a single action potential to interact with all the troponin within the cell. As a result, all the cross bridges are free to participate in the contractile response. How, then, can repetitive action potentials bring about a greater contractile response? The difference depends on how long sufficient levels of Ca^{2+} are available.

The cross bridges remain active and continue to cycle as long as enough Ca^{2+} is present to keep the troponin–tropomyosin complex away from the cross-bridge binding sites on actin. Each troponin–tropomyosin complex spans a distance of seven actin molecules. Thus, binding of Ca^{2+} to one troponin molecule leads to the uncovering of only seven cross-bridge binding sites on the thin filament.

As soon as Ca^{2+} is released in response to an action potential, the SR starts pumping Ca^{2+} back into the lateral sacs. As the cytosolic Ca^{2+} concentration declines with the re-uptake of Ca^{2+} by the lateral sacs, less Ca^{2+} is present to bind with troponin, so some of the troponin–tropomyosin complexes slip back into their blocking positions. Consequently, not all the cross-bridge binding sites remain available to participate in the cycling process during a single twitch induced by a single action potential. Because not all the cross bridges find a binding site, the resulting contraction during a single twitch is not of maximal strength.

If action potentials and twitches occur far enough apart in time for all the released Ca^{2+} from the first contractile response to be pumped back into the lateral sacs between the action potentials, an identical twitch response will occur as a result of the second action potential. If, however, a second action potential occurs and more Ca^{2+} is released while the Ca^{2+} that was

released in response to the first action potential is being taken back up, the cytosolic Ca^{2+} concentration remains elevated. This prolonged availability of Ca^{2+} in the cytosol permits more of the cross bridges to continue participating in the cycling process for a longer time. As a result, tension development increases correspondingly. As the frequency of action potentials increases, the duration of elevated cytosolic Ca^{2+} concentration increases, and contractile activity likewise increases until a maximum tetanic contraction is reached. With tetanus, the maximum number of cross-bridge binding sites remain uncovered so that cross-bridge cycling, and consequently tension development, is at its peak.

Because skeletal muscle must be stimulated by motor neurons to contract, the nervous system plays a key role in regulating contraction strength. The two main factors subject to control to accomplish gradation of contraction are the *number of motor units stimulated* and the *frequency of their stimulation*. The areas of the brain that direct motor activity combine tetanic contractions and precisely timed shifts of asynchronous motor unit recruitment to execute smooth rather than jerky contractions.

Additional factors not directly under nervous control also influence the tension developed during contraction. Among these is the length of the fibre at the onset of contraction, to which we now turn our attention.

Optimal muscle length

A relationship exists between the length of the muscle before the onset of contraction and the tetanic tension that each contracting fibre can subsequently develop at that length. For every muscle there is an **optimal length** (l_0) at which maximal force can be achieved on a subsequent tetanic contraction. More tension can be achieved during tetanus when beginning at the optimal muscle length than can be achieved when the contraction begins with the muscle less than or greater than its optimal length. This **length–tension relationship** can be explained by the sliding filament mechanism of muscle contraction.

AT OPTIMAL LENGTH (L_0)

At l_0 , when maximum tension can be developed (► Figure 7-17, point A), the thin filaments optimally overlap the regions of the thick filaments from which the cross bridges project. At this length, a maximal number of cross-bridge binding sites are accessible to the myosin molecules for binding and bending. The central region of thick filaments, where the thin filaments do not overlap at l_0 , lacks cross bridges; only myosin tails are found here.

► **FIGURE 7-17 Length-tension relationship.** Maximal tetanic contraction can be achieved when a muscle fibre is at its optimal length (l_0) before the onset of contraction, because this is the point of optimal overlap of thick-filament cross bridges and thin-filament cross-bridge binding sites (point A). The percentage of maximal tetanic contraction that can be achieved decreases when the muscle fibre is longer or shorter than l_0 before contraction. When it is longer, fewer thin-filament binding sites are accessible for binding with thick-filament cross bridges, because the thin filaments are pulled out from between the thick filaments (points B and C). When the fibre is shorter, fewer thin-filament binding sites are exposed to thick-filament cross bridges because the thin filaments overlap (point D). Also, further shortening and tension development are impeded as the thick filaments become forced against the Z lines (point D). In the body, the resting muscle length is at l_0 . Furthermore, because of restrictions imposed by skeletal attachments, muscles cannot vary beyond 30 percent of their l_0 in either direction (the range screened in light green). At the outer limits of this range, muscles still can achieve about 50 percent of their maximal tetanic contraction.

AT LENGTHS GREATER THAN l_0

At greater lengths, as when a muscle is passively stretched (point B), the thin filaments are pulled out from between the thick filaments, decreasing the number of actin sites available for cross-bridge binding; that is, some of the actin sites and cross bridges no longer match up, so they go unused. When less cross-bridge activity can occur, less tension can develop. In fact, when the muscle is stretched to about 70 percent longer than its l_0 (point C), the thin filaments are completely pulled out from between the thick filaments; this prevents cross-bridge activity, and consequently, no contraction can occur.

AT LENGTHS LESS THAN l_0

If a muscle is shorter than l_0 before contraction (point D), less tension can be developed for three reasons:

1. The thin filaments from the opposite sides of the sarcomere become overlapped, which limits the opportunity for the cross bridges to interact with actin.

2. The ends of the thick filaments become forced against the Z lines, so further shortening is impeded.
3. Besides these two mechanical factors, at muscle lengths less than 80 percent of l_0 , not as much Ca^{2+} is released during excitation-contraction coupling, for reasons unknown. Furthermore, by an unknown mechanism, the ability of Ca^{2+} to bind to troponin and pull the troponin-tropomyosin complex aside is reduced at shorter muscle lengths. Consequently, fewer actin sites are uncovered for participation in cross-bridge activity.

LIMITATIONS ON MUSCLE LENGTH

The extremes in muscle length that prevent development of tension occur only under experimental conditions, when a muscle is removed and stimulated at various lengths. In the body, the muscles are so positioned that their relaxed length is approximately their optimal length; thus, they can achieve near-maximal tetanic contraction most of the time. Because attachment to the skeleton imposes limitations, a muscle cannot be stretched or shortened more than 30 percent of its resting optimal length, and usually it deviates much less than 30 percent from normal length. Even at the outer limits (130% and 70% of l_0), the muscles still can generate half their maximum tension.

The factors we have discussed thus far that influence how much tension can be developed by a contracting muscle fibre—the frequency of stimulation and the muscle length at the onset of contraction—can vary from contraction to contraction. Other determinants of muscle fibre tension—the metabolic capability of the fibre relative to resistance to fatigue and the thickness of the fibre—do not vary from contraction to contraction but depend on the fibre type and can be modified over a period of time. After we complete our discussion of skeletal muscle mechanics, we will consider these metabolic factors in Section 7.5.

Muscle tension and bone

Tension is produced internally within the sarcomeres, considered the **contractile component** of the muscle, as a result of cross-bridge activity and the resulting sliding of filaments. However, the sarcomeres are not attached directly to the bones. Instead, the tension generated by these contractile elements must be transmitted to the bone via the connective tissue sheaths and tendons before the bone can be moved. Connective tissue sheaths and tendon, as well as other components of

the muscle, such as the intracellular titin, have a certain degree of passive elasticity. These noncontractile tissues are called the **series-elastic component** of the muscle; they behave like a stretchy spring placed between the internal tension-generating elements and the bone that is to be moved against an external load (► Figure 7-18). Shortening of the sarcomeres stretches the

series-elastic component. Muscle tension is transmitted to the bone by this tightening of the series-elastic component. This force applied to the bone moves the bone against a load.

A muscle is typically attached to at least two different bones across a joint by means of tendons that extend from each end of the muscle (► Figure 7-19). When the muscle shortens during contraction, the position of the joint is changed as one bone is moved in relation to the other—for example, *flexion* (bending) of the elbow joint by contraction of the biceps muscle and *extension* (straightening) of the elbow by contraction of the triceps. The end of the muscle attached to the more stationary part of the skeleton is called the **origin**, and the end attached to the skeletal part that moves is the **insertion**.

Not all muscle contractions shorten muscles and move bones, however. For a muscle to shorten during contraction, the tension developed in the muscle must exceed the forces that oppose movement of the bone to which the muscle's insertion is attached. In the case of elbow flexion, the opposing force—the **load**—is the weight of an object being lifted. When you flex your elbow without lifting any external object, there is still a load, albeit a minimal one—the weight of your forearm being moved against the force of gravity.

► **FIGURE 7-18** Relationship between the contractile component and the series-elastic component in transmitting muscle tension to bone. Muscle tension is transmitted to the bone by means of the stretching and tightening of the muscle's elastic connective tissue and tendon as a result of sarcomere shortening brought about by cross-bridge cycling.

Check Your Understanding 7.3

1. Describe the means by which the strength of contraction of a skeletal muscle can be changed to generate a greater overall force.
2. Describe the role of Ca^{2+} in twitch summation.
3. Explain why a muscle that has been stretched beyond its optimal length is unable to generate as much tension.

Isotonic and isometric contractions

At the level of the muscle fibre (motor unit) level, two primary types of contraction that depend on whether the muscle fibre changes length during contraction. In an **isotonic contraction** (force production is unchanged), muscle fibre tension remains constant as the muscle fibre changes length. In an **isometric contraction** (length is unchanged), the muscle fibre is prevented from shortening, so tension develops at constant muscle fibre length. The same internal events occur in both isotonic and isometric contractions: muscle fibre excitation turns on the tension-generating contractile process; the cross bridges start cycling; and filament sliding shortens the sarcomeres, which stretches the series-elastic component to exert a constant force.

Dynamic and static contractions

In contrast to muscle contraction at the level of muscle fibres, the contraction at the level of the whole muscle (e.g., biceps) requires a different consideration because muscle force varies as the muscle contracts.

© 2016 Cengage

► **FIGURE 7-19** Flexion and extension of the elbow joint

As an example, consider your biceps. Assume you are going to lift an object. When the tension developing in your biceps becomes great enough to overcome the weight of the object in your hand, you can lift the object, and the whole muscle shortens in the process. The weight of the object does not change as it is lifted, but the force exerted by the muscle changes as the muscle shortens to accommodate the change in muscle length and the joint angle throughout the range of motion; this is a dynamic (changing-force) muscle contraction.

What happens if you try to lift an object too heavy for you (i.e., if the tension you are capable of developing in your arm muscles is less than required to lift the load)? In this case, the muscle cannot shorten and lift the object but remains at constant length despite the development of tension, so a *static* (not in motion) *contraction* occurs. A static contraction is a muscle contraction that produces an increase in muscle tension but does not result in a meaningful change in body position (limb or joint displacement). In addition to occurring when the load is too great, static contractions take place when the tension developed in the muscle is deliberately less than needed to move the load. In this case, the goal is to keep the muscle at fixed length, although it can develop more tension. These submaximal static contractions are important for maintaining posture (such as keeping the legs stiff while standing) and for supporting objects in a fixed position. During a given movement, a muscle (a whole muscle, e.g., a biceps muscle) may shift between dynamic and static contractions. For example, when you pick up a book to read, your biceps undergoes a dynamic contraction while you are lifting the book, but the contraction becomes static as you stop to hold the book in front of you.

CONCENTRIC, ECCENTRIC, AND ISOMETRIC CONTRACTIONS

There are actually two types of dynamic contraction—*concentric* and *eccentric*, and one type of static contraction—*isometric*. In both cases of dynamic contraction, the whole muscle (e.g., biceps) changes length. The **concentric muscle contraction** is a dynamic contraction that produces tension during a shortening motion. This is the most familiar type of muscle contraction. During a concentric muscle contraction the actin filaments are pulled together by the myosin filaments, which move the Z lines closer together, shortening the sarcomere, and thus shortening the whole muscle. An example of a concentric muscle contraction is the action of the biceps muscle when you bend your arm at the elbow to raise a weight (e.g., a dumbbell or barbell). The **eccentric muscle contraction** is a dynamic contraction that produces tension while lengthening. In contrast to the concentric muscle contraction, during an eccentric muscle contraction the actin filaments are pulled apart, moving the Z lines farther from the centre and lengthening the sarcomere, which lengthens the whole muscle. An example of an eccentric muscle contraction is the action of the biceps muscle when you lower a weight by extending (i.e., straightening) your arm at the elbow.

In the case of static contraction, there is no change in muscle length. The **isometric contraction** is a contraction in which the muscle is activated, but instead of lengthening or shortening it is held at a constant length. An example of an isometric contraction is holding a box in front of you. Your arms (biceps muscles)

oppose gravity's downward pull on the box with equal upward force. Since your arms are neither raising nor lowering, your biceps are isometrically contracting, and there is no motion; hence, the term *static*.

OTHER TYPES OF CONTRACTIONS

Skeletal muscles are not limited to pure isotonic and isometric contractions. Muscle length and tension frequently vary throughout a range of motion. Think about pulling back a bow and arrow. The tension of your biceps muscle continuously increases to overcome the progressively increasing resistance that occurs as you stretch the bow farther. At the same time, the muscle progressively shortens as you draw the bow farther back. Such a contraction occurs at neither constant tension nor constant length.

Some skeletal muscles do not attach to bones at both ends but still produce movement. For example, the tongue muscles are not attached at the free end. Isotonic contractions of the tongue muscles manoeuvre the free, unattached portion of the tongue to facilitate speech and eating. The external eye muscles attach to the skull at their origin but to the eye at their insertion. Isotonic contractions of these muscles produce the eye movements that enable us to track moving objects, read, and so on. A few skeletal muscles are completely unattached to bone and actually prevent movement. These are the voluntarily controlled rings of skeletal muscles—known as *sphincters*—that guard the exit of urine and feces from the body by isotonically contracting.

Velocity of shortening

Force is also an important determinant of the **velocity**, or speed, of shortening (► Figure 7-20). During a concentric contraction, the greater the external force (load), the lower the velocity at which a single muscle fibre (or a constant number of contracting fibres within a muscle) shortens. The speed of shortening is maximal when there is no external force, progressively decreases with an

► **FIGURE 7-20** Force–velocity relationship in concentric contractions. The velocity of shortening decreases as the force increases.

increasing force, and falls to zero (no shortening—isometric contraction) when the force cannot be overcome by maximal tetanic tension. You have frequently experienced this **force–velocity relationship**. You can lift light objects requiring little muscle tension quickly, whereas you can lift very heavy objects only slowly, if at all. This relationship between force and shortening velocity is a fundamental property of muscle, presumably because it takes the cross bridges longer to stroke against a greater force (load).

Whereas force and velocity for shortening are *inversely* related for *concentric* contractions, force and velocity for lengthening are *directly* related for *eccentric* contractions. The greater the external force stretching a muscle that is contracting to resist the stretch, the greater is the speed with which the muscle lengthens, likely because the load breaks some of the stroking cross-bridge attachments. It is the breaking of the cross bridges of the actin and myosin molecules during eccentric muscle contractions that is associated with increased muscle damage (trauma) and a phenomenon called *delayed onset muscle soreness*.

Heat

Muscle accomplishes work in a physical sense only when an object is moved. **Work** is defined as force multiplied by distance. **Force** can be equated to the muscle tension required to overcome the load (the weight of the object). The amount of work accomplished by a contracting muscle therefore depends on how much an object weighs and how far it is moved. In an isometric contraction when no object is moved, the muscle contraction's efficiency as a producer of external work is zero. All energy consumed by the muscle during the contraction is converted to heat. In an isotonic contraction, the muscle's efficiency is about 25 percent. Of the energy consumed by the muscle during the

contraction, 25 percent is realized as external work and the remaining 75 percent is converted to heat.

Much of this heat is not really wasted in a physiological sense because it is used in maintaining the body temperature. In fact, shivering—a form of involuntarily induced skeletal muscle contraction—is a well-known mechanism for increasing heat production on a cold day. Heavy exercise on a hot day, in contrast, may overheat the body because the normal heat-loss mechanisms may be unable to compensate for this increase in heat production (Chapter 16).

Skeletal muscles, bones, and joints

Most skeletal muscles are attached to bones across joints, forming lever systems. A **lever** is a rigid structure capable of moving around a pivot point known as a **fulcrum**. In the body, the bones function as levers, the joints serve as fulcrums, and the skeletal muscles provide the force to move the bones. The portion of a lever between the fulcrum and the point where an upward force is applied is called the **power arm**; the portion between the fulcrum and the downward force exerted by a load is known as the **load arm** (► Figure 7-21a).

The most common type of lever system in the body is exemplified by flexion of the elbow joint. Skeletal muscles, such as the biceps, whose contraction flexes the elbow joint, consist of many parallel (side-by-side) tension-generating fibres that can exert a

► **FIGURE 7-21** Lever systems of muscles, bones, and joints. (a) Schematic representation of the most common type of lever system in the body, showing the location of the fulcrum, the upward force, the downward force, the power arm, and the load arm. (b) Flexion of the elbow joint as an example of lever action in the body. Note that the lever ratio (length of the power arm to length of the load arm) is 1:7 (5 cm:35 cm), which amplifies the distance and velocity of movement seven times (distance moved by the muscle [extent of shortening] = 1 cm, distance moved by the hand = 7 cm; velocity of tening = 5 cm/unit of time), but at the expense of the muscle having to exert seven times the force of the load (muscle force = 35 kg, load = 5 kg).

The dashed line in Figure 7-20 is derived from multiplying the coordinates of each point of the force–velocity curve. Thus, despite maximal force at zero velocity, the power—the product of force and velocity—is also zero. Similarly, the power is also zero at maximal velocity because force is zero. Thus, power generation is less at slow and at very fast velocities of contraction, and it peaks at intermediate velocities. This explains why bicycles are multispeed. Cyclists,

especially elite ones, maintain their pedalling frequency—equivalent to the velocity of contraction of the muscle fibres—in a range (typically 60–70 rpm) that maximizes power output. If, for example, the load increases when cycling up a hill, they shift to a lower gear ratio that allows them to maintain this pedalling frequency. Conversely, when cycling down a hill, they shift to a higher gear ratio (unless they coast to rest).

large force at their insertion but shorten only a small distance and at relatively slow velocity. The lever system of the elbow joint amplifies the slow, short movements of the biceps to produce more rapid movements of the hand that cover a greater distance.

Consider how an object weighing 5 kilograms is lifted by the hand (▶ Figure 7-21b). When the biceps contracts, it exerts an upward force at the point where it inserts on the forearm bone about 5 cm away from the elbow joint, the fulcrum. Thus, the power arm of this lever system is 5 cm long. The length of the load arm, the distance from the elbow joint to the hand, averages 35 cm. In this case, the load arm is seven times as long as the power arm, which enables the load to be moved a distance seven times as great as the shortening distance of the muscle (while the biceps shortens a distance of 1 cm, the hand moves the load a distance of 7 cm) and at a velocity seven times as great (the hand moves 7 cm during the same length of time the biceps shortens 1 cm).

The disadvantage of this lever system is that at its insertion the muscle must exert a force seven times as great as the load. The product of the length of the power arm multiplied by the upward force applied must equal the product of the length of the load arm times the downward force exerted by the load. Because the load arm multiplied by the downward force is $35\text{ cm} \times 5\text{ kg}$, the power arm multiplied by the upward force must be $5\text{ cm} \times 35\text{ kg}$ (the force that must be exerted by the muscle to be in mechanical equilibrium). Thus, skeletal muscles typically work at a mechanical disadvantage in that they must exert a considerably greater force than the actual load to be moved. Nevertheless, the amplification of velocity and distance afforded by the lever arrangement enables muscles to move loads faster over greater distances than would otherwise be possible. This amplification provides valuable manoeuvrability and speed.

Now let's shift attention from muscle mechanics to the metabolic means by which muscles power these movements.

7.5 | ATP and Fibre Types

Contractile use of ATP

Three different steps in the contraction–relaxation process require ATP:

1. Splitting of ATP on the myosin head by myosin ATPase provides the energy for the power stroke of the cross bridge.

2. Binding (but not splitting) of a fresh molecule of ATP to the myosin head lets the bridge detach from the actin filament at the end of a power stroke so that the cycle can be repeated. This ATP is later split to provide energy for the next stroke of the cross bridge.

3. Active transport of Ca^{2+} back into the SR during relaxation depends on energy derived from the breakdown of ATP.

Specific information on the metabolic pathways that generate ATP can be found in Chapter 2.

Fatigue

Contractile activity in a particular skeletal muscle cannot be maintained at a given level indefinitely. Eventually, the tension in the muscle declines as fatigue sets in. There are two different types of fatigue: muscle fatigue (sometimes called peripheral fatigue) and central fatigue.

Muscle fatigue occurs when an exercising muscle can no longer respond to stimulation with the same degree of contractile activity. Muscle fatigue is a defence mechanism that protects a muscle from reaching a point at which it can no longer produce ATP. An inability to produce ATP would result in rigor mortis (obviously not an acceptable outcome of exercise). The underlying causes of muscle fatigue are unclear. The primary implicated factors include the following:

- The *local increase in ADP and inorganic phosphate* from ATP breakdown may directly interfere with cross-bridge cycling and/or block Ca^{2+} release and uptake by the SR.
- *Accumulation of lactic acid* may inhibit key enzymes in the energy-producing pathways and/or excitation–contraction coupling process.
- The *accumulation of extracellular potassium (K^+)* that occurs in the muscle when the $\text{Na}^+ - \text{K}^+$ pump cannot actively transport K^+ back into the muscle cells as rapidly as this ion leaves during the falling phase of repeated action potentials (p. 63), causes a local reduction in membrane potential. This altered potential may decrease the release of Ca^{2+} intracellularly by impairing coupling of the voltage-gated dihydropyridine receptors in the T tubules and the Ca^{2+} -release channels in the SR.

- *Depletion of glycogen energy reserves* may lead to muscle fatigue in exhausting exercise.

The time of onset of fatigue varies with the type of muscle fibre, as some fibres are more resistant to fatigue than others. With the intensity of the exercise, more rapid onset of fatigue is associated with high-intensity activities.

Central fatigue occurs when the CNS no longer adequately activates the motor neurons supplying the working muscles. The person slows down or stops exercising even though the muscles are still able to perform. Central fatigue often is psychologically based. During strenuous exercise, central fatigue may stem from discomfort associated with the activity; it takes strong motivation (a will to win) to deliberately persevere when in pain. In less strenuous activities, central fatigue may reduce physical performance in association with boredom and monotony (such as assembly-line work) or tiredness (lack of sleep). The mechanisms involved in central fatigue are poorly understood. In some cases, central fatigue may stem from biochemical insufficiencies within the brain.

Neuromuscular fatigue in exercise—an inability of active motor neurons to synthesize acetylcholine rapidly enough to sustain chemical transmission of action potentials from the motor neurons to the muscles—can be produced experimentally but does not occur under normal physiological conditions.

Muscle fibre types within a single motor unit

The muscle fibres within a single motor unit are homogeneous in nature when they are compared on the basis of contractile and metabolic function. However, when muscle fibres from different motor units are compared, we find differences in contractile and metabolic function. In terms of contractility, muscle fibres can be classified as either **slow-twitch fibres** or **fast-twitch fibres**, and muscle fibre metabolic activity can be defined as either **glycolytic** or **oxidative**.

The slow-twitch muscle fibres are also known as **type I muscle fibres**. Type I fibres contract and relax more slowly than fast-twitch fibres, also called **type II muscle fibres**. When considering contractile (twitch) characteristics, we must also consider the motor input to the muscle fibre and the ATPase that is associated with the muscle fibre. Skeletal muscle fibre is innervated by alpha (α) motor neurons, but different α motor neurons innervate type I and type II fibres. Type I fibres are innervated by α_2 motor neurons, whereas type II fibres are innervated by α_1 motor neurons, which are larger than α_2 motor neurons. This is important because the smaller the motor neuron, the lower the activation threshold and the slower the conduction velocity of that motor unit. As a result, type I (slow-twitch) fibres are activated at lower work intensities and contract more slowly than the α_1 innervated type II fibres. Type II (fast-twitch) muscle fibres have a maximum shortening (contraction) velocity approximately 10 times greater than type I (slow-twitch) fibres.

Additionally, the importance of motor input to the muscle has been demonstrated via cross-innervation studies. If motor input to type I (α_2) and type II (α_1) fibres is reversed (switched), the contractile qualities of each muscle fibre will switch as well. Thus, type I fibres will take on the qualities of type II fibres, and vice

versa. This indicates that the contractile quality of muscle fibre is strongly influenced by the type of motor input and that muscle fibre has great plasticity. However, another important piece for understanding the contractile quality of the muscle fibre is the type of myosin ATPase located on the head of the myosin molecule. The type of ATPase correlates with the maximum velocity of shortening of the fast- and slow-twitch muscle fibres. Recall that there are different isoforms (isoforms contain the same proteins but with some small differences) of ATPase located on the myosin molecule: type II fibres have the fast form, and type I have the slow form. The difference in these ATPase isoforms is helpful in the process of muscle fibre typing via the use of a **muscle biopsy**. A muscle biopsy is the process of removing cells or tissue (muscle) using a needle for the purpose of examination under a microscope.

The metabolic properties of the two primary fibre types include oxidative and glycolytic. All muscle fibres produce energy both aerobically and anaerobically, but typically one metabolic pathway predominates within each muscle fibre (and motor unit). It is best to think of the metabolic qualities of muscle fibre as a continuum between oxidative (aerobic) and glycolytic (anaerobic). The metabolic qualities of muscle fibres are determined by staining for key glycolytic and oxidative enzymes. Type I (slow-twitch) fibres are also called *slow oxidative* because they produce their energy by aerobic processes. However, type II (fast-twitch) muscle fibres are known as either *fast oxidative glycolytic* (also known as FOG, FTa, type IIa) or *fast glycolytic* (also known as FG, FTb, type IIb, or IIx), depending on the type of enzymes associated with their metabolic processes. (See Table 7-2 for an overview of the characteristics associated with the three muscle fibre types: type I, type IIa, and type IIx.)

Depending on the muscle fibre classification method used (e.g., biochemical or myosin heavy chain), research indicates that humans do not possess type IIx, but instead have a type IIx/d. Some researchers suggest that type IIx/d (or type IIx) and type IIb are the same, but that animals have type IIb and humans possess type IIx/d. (See Ennion, S., Sant'ana Pereira, J., Sargeant, A.J., et al. [1995]. Characterization of human skeletal muscle fibres according to the myosin heavy chains they express. *J Muscle Res Cell Motil*, 16[1]: 35–43; Scott, W., Stevens, J., & Binder-Macleod, S.A. [2001]. Human skeletal muscle fiber type classifications. *Phys Ther*, 81: 1810–16.)

Other related characteristics distinguish these three fibre types—slow oxidative, fast oxidative glycolytic, and fast glycolytic. Oxidative fibres, both slow and fast, contain an abundance of mitochondria, the organelles that house the enzymes involved in oxidative phosphorylation. Because adequate oxygenation is essential to support this pathway, these fibres are richly supplied with capillaries. Oxidative fibres also have a high myoglobin content. **Myoglobin** not only helps support oxygen dependency of oxidative fibres but also gives them a red colour, just as oxygenated haemoglobin produces the red colour of arterial blood. Accordingly, these muscle fibres are called **red fibres**.

In contrast, the fast fibres specialized for glycolysis contain few mitochondria but have a high content of glycolytic enzymes instead. Also, to supply the large amounts of glucose needed for glycolysis, they contain a lot of stored glycogen. Because the glycolytic fibres need relatively less oxygen to function, they have

■ **TABLE 7-2** The Structural and Functional Characteristics Associated with the Two Types of Skeletal Muscle Fibres

	TYPE I		TYPE II
	ST	FTa	FTx
Contractile Metabolic	SO	FOG	FG
Structural Properties			
<i>Muscle fibre diameter</i>	Small	Largest	Large
<i>Mitochondrial density</i>	High	High	Low
<i>Capillary: fibre ratio</i>	High	High	Low
<i>Motor units per muscle</i>	More, smaller	Fewer, larger	Fewer, larger
<i>SR development</i>	Poor	Intermediate	High
<i>Z line development</i>	Intermediate	Wide	Narrow
Functional Properties			
<i>Twitch (contraction) time</i>	Slow	Fast	Fast
<i>Relaxation time</i>	Slow	Intermediate	Fast
<i>Force production</i>	Low	Intermediate	High
<i>Fatigability</i>	Fatigue-resistant	Fatigable	Most
<i>Axonal conduction velocity</i>	Slow	Intermediate	Fatigable
<i>Stimulus needed for peak tension</i>	Low	Intermediate	Fast
<i>Sensitivity to recruitment</i>	High	Intermediate	High
Metabolic Properties			
<i>Red colour</i>	Dark	Dark	Pale
<i>Phosphocreatine stores</i>	Low	High	High

■ Clinical Connections

McArdle's disease patients lack the enzyme myophosphorylase that catalyzes the first step in the breakdown of glycogen. Since glycogen is the primary energy source for fast, or white, fibres, and these fibres have a lesser capillary supply to deliver energy substrates, as compared to red fibres, they are more affected by this disease.

only a meagre capillary supply compared with the oxidative fibres. The glycolytic fibres contain very little myoglobin and therefore are pale in colour, so they are sometimes called **white fibres**. (The most readily observable comparison between red and white fibres is the dark and white meat in poultry.)

GENETIC ENDOWMENT OF MUSCLE FIBRE TYPES

In humans, most muscles contain a mixture of all three fibre types; the percentage of each type is largely determined by the type of activity for which the muscle is specialized. Accordingly,

a high proportion of the slow-oxidative fibres is found in muscles specialized for maintaining low-intensity contractions for long periods of time without fatigue, such as the muscles of the back and legs that support the body's weight against the force of gravity. A preponderance of fast-glycolytic fibres are found in the arm muscles, which are adapted for performing rapid, forceful movements, such as lifting heavy objects.

The percentage of these various fibres not only differs between muscles within an individual but also varies considerably among individuals. Athletes genetically endowed with a higher percentage of the fast-glycolytic fibres are good candidates for **anaerobic (high-intensity) exercise**, such as power and sprint events, whereas those with a greater proportion of slow-oxidative fibres are more likely to succeed in endurance activities, such as marathon races.

Of course, success in any event depends on many factors other than genetic endowment, such as the extent and type of training and the level of dedication. Indeed, the mechanical and metabolic capabilities of muscle fibres can change a lot in response to the patterns of demands placed on them. Let's see how.

Muscle fibre adaptation (plasticity)

Different types of exercise produce different patterns of neuronal discharge to the muscle involved. Depending on the pattern of neural activity, long-term adaptive changes occur in the muscle fibres, enabling them to respond most efficiently to the types of demands placed on the muscle. Therefore, skeletal muscle has a high degree of *plasticity* (p. 120). Two types of changes can be induced in muscle fibres: changes in their ATP synthesizing capacity, and changes in their diameter.

IMPROVEMENT IN OXIDATIVE CAPACITY

Regular **aerobic (endurance) exercise**, such as long-distance jogging or cycling, induces metabolic changes within the oxidative fibres. Physiological changes associated with long, slow exercise include increases in the number of mitochondria and increases in the number of capillaries supplying blood to these fibres. Muscles so adapted can use oxygen more efficiently and therefore can better endure prolonged activity without fatiguing. However, they do not change in size and may even atrophy following prolonged (chronic) periods of endurance training. Interestingly, evidence from McMaster University in Canada suggests that the

physiological changes in muscle thought only possible from long-distance exercise, can also be gained following high-intensity interval training (HIIT) (Gibala, M.J., McGee, S.L. [2008]. Metabolic adaptations to short-term high-intensity interval training: A little pain for a lot of gain? *Exerc & Sport Sci Rev*, 36[2]: 58–63).

MUSCLE HYPERTROPHY AND RESISTANCE TRAINING

Hypertrophy is an increase in mass or girth of a muscle and can be induced by a number of stimuli. The most familiar of these stimuli is exercise, specifically, resistance exercise (resistance training or weightlifting). For hypertrophy to occur, the message must filter down to alter the pattern of protein expression. Most research suggests that it takes approximately eight weeks of regular resistance training for actual hypertrophy to begin. However, recently, some data indicate that a small amount of hypertrophy may occur in as little as two weeks. Regardless of the precise timeline, the mechanism of hypertrophy is centred on the addition of contractile proteins to existing myofibrils. These events appear to occur within each muscle fibre (i.e., muscle cell) exercised (receives the stimuli). That is, hypertrophy results primarily from the growth of each muscle fibre, rather than an increase in the number of fibres (hyperplasia).

MUSCLE ATROPHY AND DISUSE

Muscle **atrophy** is the loss of muscle's mass, and therefore it is the opposite of muscle hypertrophy. More specifically it is a progressive withdrawal of anabolism and an increased catabolism. **Disuse atrophy** takes place when the skeletal muscles are not physically stressed on a regular basis (e.g., through weightlifting or some type of regular exercise) even though the nerve supply is intact, as when a cast or brace must be worn or during prolonged bed confinement. **Denervation atrophy** occurs after the nerve supply to a muscle is lost. If the muscle is stimulated electrically until innervation can be re established, such as during regeneration of a severed peripheral nerve, atrophy can be diminished, but not entirely prevented. Other factors that contribute to atrophy are hormonal, immunological, and nutritional. Atrophy is sometimes referred to as sarcopenia, but the term *sarcopenia* generally reflects reduced muscle regenerative ability (the reduced regeneration may be related to aging and a reduction in anabolic hormones [e.g., IGF] or disease [e.g., amyotrophic lateral sclerosis]). The end result of muscle atrophy is a decline in muscle force and power.

Why It Matters

The Benefits of Resistance Training

Multiple sclerosis (MS) is a chronic disease that attacks the CNS, with symptoms ranging from mild (e.g., numbness in the limbs) to severe (e.g., paralysis). MS is unpredictable and varies from person to person in severity and symptoms. The symptoms include fatigue, occasionally severe enough that activities of daily living (e.g., shopping) cannot be performed independently, and weakness in one or more extremities. It appears that resistance training may be beneficial in the treatment of MS. Research has shown that improved lower-limb strength

via resistance training translates into improved walking gait. Strength increases in the lower limbs likely result from neurological (e.g., synchronous recruitment pattern) changes, as well as changes in skeletal muscle fibre characteristics (e.g., hypertrophic and fibre type). Following resistance training, the gait characteristics of persons with MS more closely resemble the typical gait of those without MS. Thus, chronic resistance training may be beneficial in maintaining important characteristics of skeletal muscle function.

Functionally, reduced muscular strength and power result in a failure to preserve mobility, quality of life, and the capacity to recover from illness as we age. However, current understanding of the processes that regulate muscle mass during exercise, disuse, and rehabilitation is still somewhat unclear. For example, certain poorly understood factors released from active nerve endings, perhaps packaged with the ACh vesicles, apparently contribute to the integrity and growth of muscle tissue. Research does acknowledge that regular resistance training (e.g., weightlifting) is an important corrective measure for disuse atrophy and age-related declines in skeletal muscle mass (see also Why It Matters, p. 320).

INTERCONVERSION BETWEEN FAST MUSCLE TYPES

As previously mentioned, all the muscle fibres within a single motor unit are of the same fibre type. This pattern usually is established early in life, but the two types of fast-twitch fibres are interconvertible, depending on training efforts. Remember that fast-twitch muscle fibres are on a continuum ranging from highly glycolytic to more oxidative. That is, fast-glycolytic fibres can be converted to fast-oxidative fibres, and vice versa, depending on the types of demands repetitively placed on them. Adaptive changes in skeletal muscle gradually reverse to their original state over a period of months if the regular exercise program that induced these changes is discontinued. The default fast-twitch fibre appears to be FTb (fast-twitch glycolytic), as demonstrated in animal research (spinal transection), as well as in detraining studies (human and animal) and in the natural aging process.

Slow and fast fibres are not interconvertible, however. Although training can induce changes in muscle fibres' metabolic support systems, whether a fibre is fast or slow twitch depends on the fibre's nerve supply. Slow-twitch fibres are supplied by motor neurons that exhibit a low-frequency pattern of electrical activity, whereas fast-twitch fibres are innervated by motor neurons that display intermittent rapid bursts of electrical activity. Experimental switching of motor neurons supplying slow muscle fibres with those supplying fast fibres gradually reverses the speed at which these fibres contract.

It appears that exercise—for example, resistance training—does not increase or decrease the percentage of type I fibres a

person possesses. However, in the fast-twitch (type II) muscle fibres there is some interconversion with resistance training. Resistance training has been shown to shift type IIx to type IIa fibres. Generally, this means that following chronic resistance training, the percentage of type IIa increases, whereas the percentage of type IIx decreases.

LIMITED REPAIR OF MUSCLE

When a muscle is damaged, some limited repair is possible, even though muscle cells cannot divide mitotically to replace lost cells. A small population of inactive muscle-specific stem cells called **satellite cells** are located close to the muscle surface. When a muscle fibre is damaged, locally released factors activate the satellite cells, which divide to give rise to myoblasts. A group of myoblasts fuse to form a large, multinucleated cell, which immediately begins to synthesize and assemble the intracellular machinery characteristic of the muscle, ultimately differentiating completely into a mature muscle fibre.

Transplantation of either satellite cells or myoblasts provides one of several glimmers of hope for victims of **muscular dystrophy**—a hereditary pathological condition characterized by progressive degeneration of contractile elements, which are ultimately replaced by fibrous tissue. (See Concepts, Challenges, and Controversies, for further information on this devastating condition.)

Clinical Connections

When tissues are injured several compounds or biomarkers are released into the blood stream. One of the biomarkers specific for muscle tissue is called myoglobin. Myoglobin is the oxygen-binding protein in muscle and is related to haemoglobin, the oxygen-binding protein in blood that we discuss in Chapter 12. Myoglobin is excreted in the urine. The darkened urine that David noticed after he exercised means he had damaged his muscles. Such repetitive injury can reduce muscle mass over time.

TABLE 7-3 Determinants of Whole-Muscle Tension in Skeletal Muscle

Number of Fibres Contracting	Tension Developed by Each Contracting Fibre
Number of motor units recruited*	Frequency of stimulation (twitch summation and tetanus)*
Number of muscle fibres per motor unit	Length of fibre at onset of contraction (length–tension relationship)
Number of muscle fibres available to contract	Extent of fatigue
– Size of muscle (number of muscle fibres in muscle)	– Duration of activity
– Presence of disease (e.g., muscular dystrophy)	– Amount of asynchronous recruitment of motor units
– Extent of recovery from traumatic losses	– Type of fibre (fatigue-resistant oxidative or fatigue-prone glycolytic)
	Thickness of fibre
	– Pattern of neural activity (hypertrophy, atrophy)
	– Amount of testosterone (larger fibres in males than females)

*Factors controlled to accomplish gradation of contraction.

Muscular Dystrophy: When One Small Step Is a Big Deal

H OPE OF TREATMENT IS ON THE HORIZON for *muscular dystrophy* (MD), a muscle-wasting disease that primarily strikes boys. The most severe form can relentlessly lead to death around age 20.

Symptoms

Muscular dystrophy encompasses more than 30 distinct hereditary pathological conditions. It is part of a group of genetic, hereditary muscle diseases that are associated with a progressive weakening of the skeletal muscle. People with muscular dystrophy may have progressive skeletal muscle weakness, defects in muscle proteins, and the death of muscle cells. The gradual muscle wasting is characterized by progressive weakness over a period of years. Typically, a Duchenne MD patient begins to show symptoms of muscle weakness at about 2 to 3 years of age, becomes wheelchair bound when he is 10 to 12 years old, and dies within the next 10 years, either from respiratory failure when his respiratory muscles become too weak or from heart failure when his heart becomes too weak.

Cause

MD is caused by a recessive genetic defect on the X sex chromosome, of which males have only one copy. (Males have XY sex chromosomes; females have XX sex chromosomes.) If a male inherits from his mother an X chromosome bearing the defective dystrophic gene, he is destined to develop the disease. Duchenne MD affects 1 out of every 3500 boys worldwide. To acquire the condition, females must inherit a dystrophic-carrying X gene from both parents, a much rarer occurrence.

The defective gene responsible for *Duchenne muscular dystrophy* (DMD), the most common and most devastating form of the disease, was pinpointed in 1986. The gene normally produces **dystrophin**, a large protein that provides structural stability to the muscle cell's plasma membrane. Dystrophin is part of a complex of membrane-associated proteins that form a mechanical link between actin, a major component

of the muscle cell's internal cytoskeleton, and the extracellular matrix, an external support network (p. 34). This mechanical reinforcement of the plasma membrane enables the muscle cell to withstand the stresses and strains encountered during contraction and stretching.

Dystrophic muscles are characterized by a lack of dystrophin. Even though this protein represents only 0.002 percent of the total amount of skeletal muscle protein, its presence is crucial in maintaining the integrity of the muscle cell membrane. The absence of dystrophin permits a constant leakage of Ca^{2+} into the muscle cells. This Ca^{2+} activates proteases, protein-snipping enzymes that harm the muscle fibres. The resultant damage leads to the muscle wasting and ultimate fibrosis that characterize the disorder.

The discovery of the dystrophin gene and its deficiency in DMD brought the hope that scientists could somehow replenish this missing protein in the muscles of the disease's young victims. Although the disease is still considered untreatable and fatal, several lines of research are being pursued vigorously to intervene in the relentless muscle loss.

Gene-Therapy Approach

One approach is a possible "gene fix." With gene therapy, healthy genes are usually delivered to the defective cells by means of viruses. Viruses operate by invading a body cell and micromanaging the cell's genetic machinery. In this way, the virus directs the host cell to synthesize the proteins needed for viral replication. With gene therapy, the desired gene is inserted into an incapacitated virus that cannot cause disease but can still enter the target cell and take over genetic commands.

One of the big challenges for gene therapy for DMD is the enormity of the dystrophin gene. This gene, more than 3 million base pairs long, is the largest gene ever found. It will not fit inside the viruses usually used to deliver genes to cells—they only have enough space for a gene one-thousandth the size of the dystrophin gene. Therefore, researchers have created a minigene that is a thousand times

We have now completed our discussion of all the determinants of whole-muscle tension in a skeletal muscle, which are summarized in ■ Table 7-3. In the remaining section on skeletal muscle, we examine the central and local mechanisms involved in regulating the motor activity performed by these muscles.

Check Your Understanding 7.4

1. Describe the differences between muscle fibres in a turkey drumstick (slow-oxidative) and muscles fibres in turkey breast meat (fast-glycolytic).
2. Discuss the relative contributions of creatine phosphate, glycolysis, and oxidative phosphorylation to the production of ATP during running of a marathon.

7.6 | Control of Motor Movement

Particular patterns of motor unit output govern motor activity, ranging from maintenance of posture and balance to stereotypical locomotor movements, such as walking, to individual, highly skilled motor activity, such as gymnastics. Control of any motor movement, no matter what its level of complexity, depends on converging input to the motor neurons of specific motor units. The motor neurons, in turn, trigger contraction of the muscle fibres within their respective motor units by means of the events that occur at the neuromuscular junction.

In this section we examine the neural control of motor movement. We begin with a look at the different levels of input that

smaller than the dystrophin gene but still contains the essential components for directing the synthesis of dystrophin. This stripped-down minigene can fit inside the viral carrier. Injection of these agents has stopped and even reversed the progression of MD in experimental animals. Gene-therapy clinical trials in humans have not been completed.

Cell-Transplant Approach

Another approach involves injecting cells that can functionally rescue the dystrophic muscle tissue. Myoblasts are undifferentiated cells that fuse to form the large, multinucleated skeletal muscle cells during embryonic development. After development, a small group of stem cells known as *satellite cells* remain close to the muscle surface. Satellite cells can be activated to form myoblasts, which can fuse together to form a new skeletal muscle cell to replace a damaged cell. When the loss of muscle cells is extensive, however, as in DMD, this limited mechanism is not adequate to replace all the lost fibres.

One therapeutic approach for DMD under study involves the transplantation of dystrophin-producing myoblasts harvested from muscle biopsies of healthy donors into the patient's dwindling muscles. Other researchers are pinning their hopes on delivery of satellite cells or partially differentiated adult stem cells that can be converted into healthy muscle cells (p. 11). The aetiology and treatments for MD are under investigation by Drs. J. Tremblay (Human Genetics Institute, University of Laval) and R. Worton (Ottawa Health Research Institute). Dr. Tremblay conducts research associated with cell transplant, and Dr. Worton's research is in the area of gene therapy.

Utrophin Approach

An alternative strategy that holds considerable promise for treating DMD is upregulation of **utrophin**, a naturally occurring protein in

muscle that is closely related to dystrophin. Eighty percent of the amino acid sequence for dystrophin and utrophin is identical, but these two proteins normally have different functions. Whereas dystrophin is dispersed throughout the muscle cell's surface membrane, where it contributes to the membrane's structural stability, utrophin is concentrated at the motor end plate. Here, utrophin plays a role in anchoring the acetylcholine receptors.

When researchers genetically engineered dystrophin-deficient mice that produced extra amounts of utrophin, this utrophin upregulation compensated in large part for the absent dystrophin; that is, the additional utrophin dispersed throughout the muscle cell membrane, where it assumed dystrophin's responsibilities. The result was improved intracellular Ca^{2+} homeostasis, enhanced muscle strength, and a marked reduction in the microscopic signs of muscle degeneration. Researchers are now scrambling to find a drug that will entice muscle cells to overproduce utrophin in humans, in the hopes of preventing or even repairing the muscle wasting that characterizes this devastating condition.

These steps toward an eventual treatment mean that hopefully one day the afflicted boys will be able to take steps on their own instead of being destined to wheelchairs and early death.

control motor output and discuss how these are integrated. Then we take a closer look at the skeletal muscle receptors that form the afferent inputs.

Neural input

Three levels of input control motor-neuron output (► Figure 7-22).

1. *Input from afferent neurons*, usually through intervening interneurons, at the level of the spinal cord—that is, spinal reflexes (p. 107).
2. *Input from the primary motor cortex*. Fibres originating from neuronal cell bodies, known as **pyramidal cells**, within the primary motor cortex (p. 115) descend directly

without synaptic interruption to terminate on motor neurons (or on local interneurons that terminate on motor neurons) in the spinal cord. These fibres make up the **corticospinal (pyramidal) motor system**.

3. *Input from the brain stem* as part of the multineuronal motor system. The pathways composing the **multineuronal (extrapyramidal) motor system** include a number of synapses that involve many regions of the brain (*extra* means “outside of”; *pyramidal* refers to the pyramidal system). The final link in multineuronal pathways is the brain stem, especially the reticular formation (p. 110), which in turn is influenced by motor regions of the cortex,

the cerebellum, and the basal nuclei. In addition, the motor cortex itself is interconnected with the thalamus as well as with premotor and supplementary motor areas, all part of the multilineuronal system.

The only brain regions that directly influence motor neurons are the primary motor cortex and brain stem; the other involved brain regions indirectly regulate motor activity by adjusting

motor output from the motor cortex and brain stem. A number of complex interactions take place among these various brain regions; the most important are represented in ▶ Figure 7-22. (See Chapter 3 for further discussion of the specific roles and interactions of these brain regions.)

Spinal reflexes involving afferent neurons are important in maintaining posture and in executing basic protective movements, such as the withdrawal reflex. The corticospinal system

From Sherwood, Human Physiology, 8E. © 2013 Brooks/Cole, a part of Cengage, Inc. Reproduced by permission. www.cengage.com/permissions

primarily mediates performance of fine, discrete, voluntary movements of the hands and fingers, such as those required for doing intricate needlework. Premotor and supplementary motor areas, with input from the cerebrotocerebellum, plan the voluntary motor command that is issued to the appropriate motor neurons by the primary motor cortex through this descending system. The multineuronal system, in contrast, primarily regulates overall body posture involving involuntary movements of large muscle groups of the trunk and limbs. The corticospinal and multineuronal systems show considerable complex interaction and overlapping of function. To voluntarily manipulate your fingers to do needlework, for example, you subconsciously assume a particular posture of your arms that lets you hold your work.

Some of the inputs converging on motor neurons are excitatory, whereas others are inhibitory. Coordinated movement depends on an appropriate balance of activity in these inputs. The following types of motor abnormalities result from defective motor control:

- 

If an inhibitory system originating in the brain stem is disrupted, muscles become hyperactive because of the unopposed activity in excitatory inputs to motor neurons. This condition, characterized by increased muscle tone and augmented limb reflexes, is known as **spastic paralysis**.
- In contrast, loss of excitatory input, such as that accompanying destruction of descending excitatory pathways exiting the primary motor cortex, brings about **flaccid paralysis**. In this condition, the muscles are relaxed, and the person cannot voluntarily contract muscles, although spinal reflex activity is still present. Damage to the primary motor cortex on one side of the brain, as with a stroke, leads to flaccid paralysis on the opposite half of the body (**hemiplegia**, or paralysis of one side of the body). Disruption of all descending pathways, as in traumatic severance of the spinal cord, produces flaccid paralysis below the level of the damaged region—**tetraplegia** (a.k.a. quadriplegia; paralysis of all four limbs) in upper spinal cord damage and **paraplegia** (paralysis of the legs) in lower spinal cord injury.
- Destruction of motor neurons—either their cell bodies or efferent fibres—causes flaccid paralysis and lack of reflex responsiveness in the affected muscles.
- Damage to the cerebellum or basal nuclei does not result in paralysis but instead in uncoordinated, clumsy activity and inappropriate patterns of movement. These regions normally smooth out activity initiated voluntarily.
- Damage to higher cortical regions involved in planning motor activity results in the inability to establish appropriate motor commands to accomplish desired goals.

Afferent information

Coordinated, purposeful skeletal muscle activity depends on afferent input from a variety of sources. At a simple level, afferent signals indicating that your finger is touching a hot stove trigger reflex contractile activity in appropriate arm muscles to withdraw the hand from the injurious stimulus. At a more complex

level, if you are going to catch a ball, the motor systems of your brain must program sequential motor commands that will move and position your body correctly for the catch, using predictions of the ball's direction and rate of movement provided by visual input. Many muscles acting simultaneously or alternately at different joints are called into play to shift your body's location and position rapidly, while maintaining your balance in the process. It is critical to have ongoing input about your body position with respect to the surrounding environment, as well as the position of your various body parts in relationship to one another. This information is necessary for establishing a neuronal pattern of activity to perform the desired movement. To appropriately program muscle activity, your CNS must know the starting position of your body. Further, it must be constantly informed about the progression of movement it has initiated, so that it can make adjustments as needed. Your brain receives this information, which is known as proprioceptive input (p. 117), from receptors in your eyes, joints, vestibular apparatus, and skin, as well as from the muscles themselves.

You can demonstrate your joint and muscle proprioceptive receptors in action by closing your eyes and bringing the tips of your right and left index fingers together at any point in space. You can do so without seeing where your hands are, because your brain is informed of the position of your hands and other body parts at all times by afferent input from the joint and muscle receptors.

Two types of muscle receptors—*muscle spindles* and *Golgi tendon organs*—monitor changes in muscle length and tension. Muscle length is monitored by muscle spindles; changes in muscle tension are detected by Golgi tendon organs. Both these receptor types are activated by muscle stretch, but they convey different types of information. Let us see how.

MUSCLE SPINDLE STRUCTURE

Muscle spindles, which are distributed throughout the fleshy part of a skeletal muscle, consist of collections of specialized muscle fibres known as **intrafusal fibres**. These fibres lie within spindle-shaped connective tissue capsules parallel to the **extrafusal fibres** (*fusus* means “spindle”) (▶ Figure 7-23). Unlike an extrafusal skeletal muscle fibre, which contains contractile elements (myofibrils) throughout its entire length, an intrafusal fibre has a noncontractile central portion, with the contractile elements being limited to both ends.

Each muscle spindle has its own private efferent and afferent nerve supply. The efferent neuron that innervates a muscle spindle's intrafusal fibres is known as a **gamma motor neuron**, whereas the motor neurons that supply the extrafusal fibres are called **alpha motor neurons**. Two types of afferent sensory endings terminate on the intrafusal fibres and serve as muscle spindle receptors, both of which are activated by stretch. The **primary (annulospiral) endings** are wrapped around the central portion of the intrafusal fibres; they detect changes in the length of the fibres during stretching as well as the speed with which it occurs. The **secondary (flower-spray) endings**, which are clustered at the end segments of many of the intrafusal fibres, are sensitive only to changes in length. Muscle spindles play a key role in the stretch reflex (p. 106).

► **FIGURE 7-23 Muscle spindle.** A muscle spindle consists of a collection of specialized intrafusal fibres that lie within a connective tissue capsule parallel to the extrafusal skeletal muscle fibres. The muscle spindle is innervated by its own gamma motor neuron and is supplied by two types of afferent sensory terminals: the primary (annulospiral) endings, and the secondary (flower-spray) endings, both of which are activated by stretch.

GOLGI TENDON ORGANS

In contrast to muscle spindles, which lie within the belly of the muscle, **Golgi tendon organs** are in the tendons of the muscle, where they can respond to changes in the muscle's tension rather than to changes in its length. Because a number of factors determine the tension developed in the whole muscle during contraction (e.g., frequency of stimulation or length of the muscle at the onset of contraction), it is essential that motor control systems be apprised of the tension actually achieved so that adjustments can be made as necessary.

The Golgi tendon organs consist of endings of afferent fibres entwined within bundles of connective tissue fibres that make up the tendon. When the extrafusal muscle fibres contract, the resulting pull on the tendon tightens the connective tissue bundles, which in turn increase the tension exerted on the bone to which the tendon is attached. In the process, the entwined Golgi organ afferent receptor endings are stretched, causing the afferent fibres to fire; the frequency of firing is directly related to the tension developed. This afferent information is sent to the brain for processing. Much of this information is used subconsciously for smoothly executing motor activity, but unlike afferent information from the muscle spindles, afferent information from the Golgi tendon organ reaches the level of conscious awareness. You are aware of the tension within a muscle but not of its length.

Scientists once thought the Golgi tendon organ triggered a protective spinal reflex that halted further contraction and brought about sudden reflex relaxation when the muscle tension became great enough, thus helping prevent damage to the muscle

or tendon from excessive, tension-developing muscle contractions. Scientists now believe, however, that this receptor is a pure sensor and does not initiate any reflexes. Other unknown mechanisms are apparently involved in inhibiting further contraction to prevent tension-induced damage.

Having completed our discussion of skeletal muscle, we turn our attention to smooth and cardiac muscle.

7.7 | Smooth and Cardiac Muscle

The two other types of muscle—**smooth muscle** and **cardiac muscle**—share some basic properties with skeletal muscle, but each also displays unique characteristics (■ Table 7-4). To accomplish contraction, each of the three muscle types has a specialized contractile apparatus made up of thin actin filaments that slide relative to stationary thick myosin filaments in response to a rise in cytosolic Ca^{2+} . As well, they all directly use ATP as the energy source for cross-bridge cycling. However, the structure and organization of fibres within these different muscle types vary, as do their mechanisms of excitation and the means by which excitation and contraction are coupled. Furthermore, there are important distinctions in the contractile response itself. In this section, we highlight the unique features of smooth and cardiac muscle, as compared with skeletal muscle. There is a detailed discussion of their function in later chapters that focus on the

■ **TABLE 7-4** Comparison of Muscle Types

Characteristic	TYPE OF MUSCLE			
	Skeletal	Multiunit Smooth	Single-Unit Smooth	Cardiac
Location	Attached to skeleton	Large blood vessels, small airways, eye, and hair follicles	Walls of hollow organs in digestive, reproductive, and urinary tracts and in small blood vessels	Heart only
Function	Movement of body in relation to external environment	Varies with structure involved	Movement of contents within hollow organs	Pumps blood out of heart
Mechanism of Contraction	Sliding filament mechanism	Sliding filament mechanism	Sliding filament mechanism	Sliding filament mechanism
Innervation	Somatic nervous system (alpha motor neurons)	Autonomic nervous system	Autonomic nervous system	Autonomic nervous system
Level of Control	Under voluntary control; also subject to subconscious regulation	Under involuntary control	Under involuntary control	Under involuntary control
Initiation of Contraction	Neurogenic	Neurogenic	Myogenic (pacemaker potentials and slow-wave potentials)	Myogenic (pacemaker potentials)
Role of Nervous Stimulation	Initiates contraction; accomplishes gradation	Initiates contraction; contributes to gradation	Modifies contraction; can excite or inhibit; contributes to gradation	Modifies contraction; can excite or inhibit; contributes to gradation
Modifying Effect of Hormones	No	Yes	Yes	Yes
Presence of Thick Myosin and Thin Actin Filaments	Yes	Yes	Yes	Yes
Striated by Orderly Arrangement of Filaments	Yes	No	No	Yes
Presence of Troponin and Tropomyosin	Yes	Tropomyosin only	Tropomyosin only	Yes
Presence of T Tubules	Yes	No	No	Yes
Level of Development of Sarcoplasmic Reticulum	Well developed	Poorly developed	Poorly developed	Moderately developed
Cross Bridges Turned on by Ca^{2+}	Yes	Yes	Yes	Yes
Source of Increased Cytosolic Ca^{2+}	Sarcoplasmic reticulum	Extracellular fluid and sarcoplasmic reticulum	Extracellular fluid and sarcoplasmic reticulum	Extracellular fluid and sarcoplasmic reticulum
Site of Ca^{2+} Regulation	Troponin in thin filaments	Myosin in thick filaments	Myosin in thick filaments	Troponin in thin filaments
Mechanism of Ca^{2+} Action	Physically repositions troponin–tropomyosin complex to uncover actin cross-bridge binding sites	Chemically brings about phosphorylation of myosin cross bridges so they can bind with actin	Chemically brings about phosphorylation of myosin cross bridges so they can bind with actin	Physically repositions troponin–tropomyosin complex

7

organs containing these muscle types. We begin by describing the two categories of smooth muscle—multiunit and single-unit smooth muscle—that are based on differences in how the muscle fibres become excited.

Multiunit smooth muscle

Multiunit smooth muscle exhibits properties partway between those of skeletal muscle and single-unit smooth muscle. As the name implies, a multiunit smooth muscle consists of multiple discrete units that function independently of one another and must be separately stimulated by nerves to contract, similar to skeletal muscle motor units. Therefore, contractile activity in both skeletal muscle and multiunit smooth muscle is **neurogenic** (nerve produced). That is, contraction in these muscle types is initiated only in response to stimulation by the nerves supplying the muscle. Whereas skeletal muscle is innervated by the voluntary somatic nervous system (motor neurons), multiunit (as well as single-unit) smooth muscle is supplied by the involuntary autonomic nervous system.

Multiunit smooth muscle is found (1) in the walls of large blood vessels; (2) in small airways to the lungs; (3) in the muscle of the eye that adjusts the lens for near or far vision; (4) in the iris of the eye, which alters the pupil size to adjust the amount of light entering the eye; and (5) at the base of hair follicles, contraction of which causes goosebumps.

Single-unit smooth muscle cells and functional syncytia

Most smooth muscle is **single-unit smooth muscle**, alternatively called **visceral smooth muscle**, because it is found in the walls of the hollow organs or viscera (e.g., the digestive, reproductive, and urinary tracts and small blood vessels). The term *single-unit smooth muscle* derives from the fact that the muscle fibres that make up this type of muscle become excited and contract as a single unit. The muscle fibres in single-unit smooth muscle are electrically linked by gap junctions (p. 35). When an action potential occurs anywhere within a sheet of single-unit smooth muscle, it is quickly propagated via these special points of electrical contact throughout the entire group of interconnected cells, which then contract as a single, coordinated unit. Such a group of interconnected muscle cells that function electrically and mechanically as a unit is known as a **functional syncytium** (plural, *syncytia*; *syn* means “together”; *cyt* means “cell”).

Thinking about the role of the uterus during labour can help you appreciate the significance of this arrangement. Muscle cells composing the uterine wall act as a functional syncytium. They repeatedly become excited and contract as a unit during labour, exerting a series of coordinated “pushes” that eventually deliver the baby. Independent, uncoordinated contractions of individual muscle cells in the uterine wall could not exert the uniformly applied pressure needed to expel the baby. Single-unit

smooth muscle elsewhere in the body is arranged in similar functional syncytia.

Smooth muscle cells: Small and unstriated

Most smooth muscle cells are found in the walls of hollow organs and tubes. Their contraction exerts pressure on and regulates the forward movement of the contents of these structures.

Both smooth and skeletal muscle cells are elongated, but in contrast to their large, cylindrical skeletal muscle counterparts, smooth muscle cells are spindle shaped, have a single nucleus, and are considerably smaller (2 to 10 μm in diameter and 50 to 400 μm long). Also unlike skeletal muscle cells, a single smooth muscle cell does not extend the full length of a muscle. Instead, groups of smooth muscle cells are typically arranged in sheets (► Figure 7-24a).

A smooth muscle cell has three types of filaments: (1) thick myosin filaments, which are longer than those in skeletal muscle;

(2) thin actin filaments, which contain tropomyosin but lack the regulatory protein troponin; and (3) filaments of intermediate size, which do not directly participate in contraction but are part of the cytoskeletal framework that supports the cell shape. Smooth muscle filaments do not form myofibrils and are not arranged in the sarcomere pattern found in skeletal muscle. Thus, smooth muscle cells do not show the banding or striation of skeletal muscle, hence the term *smooth* for this muscle type.

Lacking sarcomeres, smooth muscle does not have Z lines, but instead has **dense bodies** containing the same protein constituent found in Z lines (► Figure 7-24b). Dense bodies are positioned throughout the smooth muscle cell as well as attached to the internal surface of the plasma membrane. The actin filaments are anchored to the dense bodies. Considerably more actin is present in smooth muscle cells than in skeletal muscle cells, with 10 to 15 thin filaments for each thick myosin filament in smooth muscle compared with 2 thin filaments for each thick filament in skeletal muscle.

The thick- and thin-filament contractile units are oriented slightly diagonally from side to side within the smooth muscle cell in an elongated, diamond-shaped lattice, rather than running parallel with the long axis as myofibrils do in skeletal muscle (► Figure 7-25a). Relative sliding of the thin filaments past the thick filaments during contraction causes the filament lattice to shorten and expand from side to side. As a result, the whole cell shortens and bulges out between the points where the thin filaments are attached to the inner surface of the plasma membrane (► Figure 7-25b).

► **FIGURE 7-24** Microscopic view of smooth muscle cells. (a) Low-power light micrograph of smooth muscle cells. Note the spindle shape and single, centrally located nucleus. (b) Electron micrograph of smooth muscle cells at 14 000 $\times$ magnification. Note the presence of dense bodies and lack of banding.

Smooth muscle cells and calcium

The thin filaments of smooth muscle cells do not contain troponin, and tropomyosin does not block actin's cross-bridge binding sites. So we have two questions: What prevents actin and myosin from binding at the cross bridges in the resting state? And how is cross-bridge activity switched on in the excited state? Light-weight chains of proteins are attached to the heads of myosin molecules. These so-called **light chains** are only of secondary importance in skeletal muscle, but they have a crucial regulatory function in smooth muscle. The smooth muscle myosin heads can interact with actin only when the myosin light chain is *phosphorylated* (i.e., has a phosphate group from ATP attached to it). During excitation, the increased cytosolic Ca^{2+} acts as an intracellular messenger, initiating a chain of biochemical events that results in phosphorylation of the myosin light chain (► Figure 7-26). Smooth muscle Ca^{2+} binds with **calmodulin**, an intracellular protein found in most cells that is structurally similar to troponin (p. 302). This Ca^{2+} -calmodulin complex binds to and activates another protein, **myosin light chain kinase (MLC kinase)**, which in turn phosphorylates the myosin light chain. Thus phosphorylated, the myosin cross bridge is able to bind with actin so that cross-bridge cycling can begin. In this way, smooth muscle is triggered to contract by a rise in cytosolic Ca^{2+} similar to what happens in skeletal muscle. In smooth muscle, however, Ca^{2+} ultimately turns on the cross bridges by inducing a *chemical* change in myosin in the

► **FIGURE 7-25** Schematic representation of the arrangement of thick and thin filaments in a smooth muscle cell in contracted and relaxed states. (a) Relaxed smooth muscle cell. (b) Contracted smooth muscle cell

thick filaments, whereas in skeletal muscle it exerts its effects by invoking a *physical* change at the *thin* filaments (► Figure 7-27). Recall that in skeletal muscle, Ca^{2+} moves troponin and tropomyosin from their blocking position, so actin and myosin are free to bind with each other.

The way excitation increases cytosolic Ca^{2+} concentration in smooth muscle cells also differs from that for skeletal muscle. A smooth muscle cell has no T tubules and a poorly developed SR. The increased cytosolic Ca^{2+} that triggers the contractile response comes from two sources: most Ca^{2+} enters from the ECF, but some is released intracellularly from the sparse SR stores. Unlike their role in skeletal muscle cells, voltage-gated dihydropyridine receptors in the plasma membrane of smooth muscle cells function as Ca^{2+} channels. When these surface-membrane channels are opened, Ca^{2+} enters down its concentration gradient from the ECF. The entering Ca^{2+} triggers the opening of Ca^{2+} channels in the SR so that small additional amounts of Ca^{2+} are released intracellularly from this meagre source. Because smooth muscle cells are so much smaller in diameter than skeletal muscle fibres, most Ca^{2+} entering from the ECF can influence cross-bridge activity, even in the central portions of the cell, without requiring an elaborate T tubule–SR mechanism.

Relaxation is accomplished by removal of Ca^{2+} as it is actively transported out across the plasma membrane and back into the SR. When Ca^{2+} is removed, myosin is dephosphorylated (the phosphate is removed) and can no longer interact with actin, so the muscle relaxes.

We are about to address the second question, How does smooth muscle become excited to contract—that is, what opens the Ca^{2+} channels in the plasma membrane? First we discuss the myogenic activity of single-unit smooth muscle.

Single-unit smooth muscle: Myogenic

Single-unit smooth muscle is **self-excitable**, so it does not require nervous stimulation for contraction. Clusters of specialized smooth muscle cells within a functional syncytium display spontaneous

► **FIGURE 7-26** Calcium activation of myosin cross bridge in smooth muscle

► **FIGURE 7-27** Comparison of the role of calcium in bringing about contraction in smooth muscle and skeletal muscle

electrical activity; that is, they can undergo action potentials without any external stimulation. In contrast to the other excitable cells we have been discussing (such as neurons, skeletal muscle fibres, and multiunit smooth muscle), the self-excitable cells of single-unit smooth muscle do not maintain a constant resting potential. Instead, their membrane potential inherently fluctuates without any influence by factors external to the cell. Two major types of spontaneous depolarizations displayed by self-excitable cells are *pacemaker potentials* and *slow-wave potentials*.

PACEMAKER POTENTIALS

With **pacemaker potentials**, the membrane potential gradually depolarizes on its own because of shifts in passive ionic fluxes accompanying automatic changes in channel permeability (► Figure 7-28a). When the membrane has depolarized to threshold, an action potential is initiated. After repolarizing, the membrane potential once again depolarizes to threshold, cyclically continuing in this manner to repetitively self-generate action potentials.

SLOW-WAVE POTENTIALS

Slow-wave potentials are gradually alternating hyperpolarizing and depolarizing swings in potential caused by automatic cyclic changes in the rate at which sodium ions are actively transported

► **FIGURE 7-28** Self-generated electrical activity in smooth muscle.

(a) With pacemaker potentials, the membrane gradually depolarizes to threshold on a regular periodic basis without any nervous stimulation. These regular depolarizations cyclically trigger self-induced action potentials. (b) In slow-wave potentials, the membrane gradually undergoes self-induced hyperpolarizing and depolarizing swings in potential. A burst of action potentials occurs if a depolarizing swing brings the membrane to threshold.

across the membrane (► Figure 7-28b). The potential is moved farther from threshold during each hyperpolarizing swing and closer to threshold during each depolarizing swing. If threshold is reached, a burst of action potentials occurs at the peak of a depolarizing swing. Threshold is not always reached, however, so the oscillating slow-wave potentials can continue without generating action potentials. Whether threshold is reached depends on the starting point of the membrane potential at the onset of its depolarizing swing. The starting point, in turn, is influenced by neural and local factors.

We have now discussed all the means by which excitable tissues can be brought to threshold. ■ Table 7-5 summarizes the different triggering events that can initiate action potentials in various excitable tissues.

MYOGENIC ACTIVITY

Self-excitable smooth muscle cells are specialized to initiate action potentials, but they are not equipped to contract. Only a very few of all the cells in a functional syncytium are

■ **TABLE 7-5** Various Means of Initiating Action Potentials in Excitable Tissues

Method of Depolarizing the Membrane to Threshold Potential	Type of Excitable Tissue Involved	Description of This Triggering Event
Summation of Excitatory Postsynaptic Potentials (EPSPs) (p. 76)	Efferent neurons, interneurons	Temporal or spatial summation of slight depolarizations (EPSPs) of the dendrite/cell body end of the neuron brought about by changes in channel permeability in response to binding of excitatory neurotransmitter with surface membrane receptors
Receptor Potential (p. 144)	Afferent neurons	Typically a depolarization of the afferent neuron's receptor initiated by changes in channel permeability in response to the neuron's adequate stimulus
End-plate Potential (p. 197)	Skeletal muscle	Depolarization of the motor end plate brought about by changes in channel permeability in response to binding of the neurotransmitter acetylcholine with receptors on the end-plate membrane
Pacemaker Potential (p. 331)	Smooth muscle, cardiac muscle	Gradual depolarization of the membrane on its own because of shifts in passive ionic fluxes accompanying automatic changes in channel permeability
Slow-Wave Potential (p. 331)	Smooth muscle (in digestive tract only)	Gradual alternating hyperpolarizing and depolarizing swings in potential caused by automatic cyclical changes in active ionic transport across the membrane

noncontractile, pacemaker cells. These cells are typically clustered in a specific location. The vast majority of smooth muscle cells in a functional syncytium are specialized to contract but cannot self-initiate action potentials. However, once an action potential is initiated by a self-excitable smooth muscle cell, it is conducted to the remaining contractile, nonpacemaker cells of the functional syncytium via gap junctions, so the entire group of connected cells contracts as a unit without any nervous input. Such nerve-independent contractile activity initiated by the muscle itself is called **myogenic** (muscle-produced) activity, in contrast to the neurogenic activity of skeletal muscle and multi-unit smooth muscle.

Gradation of single-unit smooth muscle contraction

Single-unit smooth muscle differs from skeletal muscle in the way contraction is graded. Gradation of skeletal muscle contraction is entirely under neural control, primarily involving motor unit recruitment and twitch summation. In smooth muscle, gap junctions ensure that an entire smooth muscle mass contracts as a single unit, making it impossible to vary the number of muscle fibres contracting. Only the tension of the fibres can be modified to achieve varying strengths of contraction of the whole organ. The portion of cross bridges activated and the tension subsequently developed in single-unit smooth muscle can be graded by varying the cytosolic Ca^{2+} concentration. A single excitation in smooth muscle does not cause all the cross bridges to switch on, in contrast to skeletal muscles, where a single action potential triggers release of enough Ca^{2+} to permit all cross bridges to

cycle. As Ca^{2+} concentration increases in smooth muscle, more cross bridges are brought into play, and greater tension develops.

SMOOTH MUSCLE TONE

Many single-unit smooth muscle cells have sufficient levels of cytosolic Ca^{2+} to maintain a low level of tension, or **tone**, even in the absence of action potentials. A sudden drastic change in Ca^{2+} , such as that which accompanies a myogenically induced action potential, brings about a contractile response superimposed on the ongoing tonic tension. Besides self-induced action potentials, a number of other factors, including autonomic neurotransmitters, can influence contractile activity and the development of tension in smooth muscle cells by altering their cytosolic Ca^{2+} concentration.

MODIFICATION OF SMOOTH MUSCLE ACTIVITY BY THE AUTONOMIC NERVOUS SYSTEM

Smooth muscle is typically innervated by both branches of the autonomic nervous system. In single-unit smooth muscle, this nerve supply does not *initiate* contraction, but it can *modify* the rate and strength of contraction, either enhancing or retarding the inherent contractile activity of a given organ. Recall that the isolated motor end-plate region of a skeletal muscle fibre interacts with ACh released from a single axon terminal of a motor neuron. In contrast, the receptor proteins that bind with autonomic neurotransmitters are dispersed throughout the entire surface membrane of a smooth muscle cell. Smooth muscle cells are sensitive to varying degrees and in varying ways to autonomic neurotransmitters, depending on the cells' distributions of cholinergic and adrenergic receptors (pp. 192–193).

Each terminal branch of a postganglionic autonomic fibre travels across the surface of one or more smooth muscle cells, releasing neurotransmitter from the vesicles within its multiple varicosities (bulges) as an action potential passes along the terminal (► Figure 7-29). The neurotransmitter diffuses to the many receptor sites specific for it on the cells underlying the terminal. Thus, in contrast to the discrete one-to-one relationship at motor end plates, a given smooth muscle cell can be influenced by more than one type of neurotransmitter, and each autonomic terminal can influence more than one smooth muscle cell.

► **FIGURE 7-29** Schematic representation of innervation of smooth muscle by autonomic postganglionic nerve terminals

OTHER FACTORS INFLUENCING SMOOTH MUSCLE ACTIVITY

Other factors (besides autonomic neurotransmitters) can influence the rate and strength of both multiunit and single-unit smooth muscle contraction, including mechanical stretch, certain hormones, local metabolites, and specific drugs. All these factors ultimately act by modifying the permeability of Ca^{2+} channels in the plasma membrane, the SR, or both, through a variety of mechanisms. Thus, smooth muscle is subject to more external influences than skeletal muscle is, even though smooth muscle can contract on its own and skeletal muscle cannot.

Next, we look in detail at the length–tension relationship in smooth muscle, but only in regard to the effect of mechanical stretch on smooth muscle contractility. We will examine the extracellular chemical influences on smooth muscle contractility in later chapters when we discuss regulation of the various organs that contain smooth muscle.

Smooth muscle: Tension and relaxation

The relationship between the length of the muscle fibres before contraction and the tension that can be developed on a subsequent contraction is less closely linked in smooth muscle than in skeletal muscle. Smooth muscle can have one of two different responses to being stretched: (1) being able to develop tension even when considerably stretched, and (2) inherently relaxing when stretched. The range of lengths over which a smooth muscle fibre can develop near-maximal tension is much greater than for skeletal muscle. Smooth muscle can still develop considerable tension even when stretched up to 2.5 times its resting length, for two likely reasons. First, in contrast to skeletal muscle, in which the resting length is at l_0 , in smooth muscle the resting (nonstretched) length is much shorter than at l_0 . Therefore, smooth muscle can be stretched considerably before reaching its optimal length. Second, the

thin filaments in smooth muscle cells continue to overlap the much longer thick filaments even in the stretched-out position, so cross-bridge interaction and tension development can still take place. In contrast, when skeletal muscle is stretched only three-fourths longer than its resting length, the thick and thin filaments are completely pulled apart and can no longer interact (see ► Figure 7-17).

The ability of a considerably stretched smooth muscle fibre to continue to develop tension is important, because the smooth muscle fibres within the wall of a hollow organ are progressively stretched as the volume of the organ's contents expands. Consider the urinary bladder as an example. Even though the muscle fibres in the urinary bladder are stretched as the bladder gradually fills with urine, they maintain their tone and can even develop further tension in response to inputs that regulate bladder emptying. If considerable stretching prevented tension development, as in skeletal muscle, a filled bladder would not be capable of contracting to empty.

STRESS RELAXATION RESPONSE

When a smooth muscle is suddenly stretched, it initially increases its tension, much like the tension created in a stretched rubber band. The muscle quickly adjusts to this new length, however, and inherently relaxes to the tension level prior to the stretch, probably as a consequence of rearrangement of cross-bridge attachments. Smooth muscle cross bridges detach comparatively slowly. Some researchers speculate that, on sudden stretching of smooth muscle, any attached cross bridges would strain against the stretch, thereby contributing to a passive (not actively generated) increase in tension. As these cross bridges detach, the filaments would be able to slide into an unstrained stretched position, restoring the tension to its original level. This inherent property of smooth muscle is called the **stress relaxation response**.

ADVANTAGES OF THE SMOOTH MUSCLE LENGTH-TENSION RELATIONSHIP

These two responses of smooth muscle to being stretched—being able to develop tension even when considerably stretched and inherently relaxing when stretched—are highly advantageous. They enable smooth muscle to exist at a variety of lengths with little change in tension. As a result, a hollow organ enclosed by smooth muscle can accommodate variable volumes of contents with little change in the pressure exerted on the contents except when the contents are to be pushed out of the organ. At that time, the tension is deliberately increased by fibre shortening. It is possible for smooth muscle fibres to contract to half their normal length, enabling hollow organs to dramatically empty their contents on increased contractile activity; thus, smooth-muscle viscera can easily accommodate large volumes but can empty to practically zero volume. This length range in which smooth muscle normally functions (anywhere from 0.5 to 2.5 times the normal length) is much greater than the limited length range within which skeletal muscle remains functional.

Smooth muscle contains a lot of connective tissue, which resists being stretched. Unlike skeletal muscle, in which the skeletal attachments restrict how far the muscle can be stretched, this connective tissue prevents smooth muscle from being over-stretched and thus puts an upper limit on how much a smooth-muscle hollow organ can hold.

Smooth muscle: Slow and economical

A smooth muscle contractile response proceeds more slowly than a skeletal muscle twitch. A single smooth muscle contraction may last as long as three seconds (3000 msec), compared with the maximum of 100 msec required for a single contractile response in skeletal muscle. ATP splitting by myosin ATPase is much slower in smooth muscle, so cross-bridge activity and filament sliding occur more slowly. Smooth muscle also relaxes more slowly because of slower Ca^{2+} removal. Slowness should not be equated with weakness, however. Smooth muscle can generate the same contractile tension per unit of cross-sectional area as skeletal muscle, but it does so more slowly and at considerably less energy expense. Because of slow cross-bridge cycling during smooth muscle contraction, cross bridges stay attached for more time during each cycle, compared with skeletal muscle; that is, the cross bridges latch onto the thin filaments for a longer time each cycle. This so-called **latch phenomenon** enables smooth muscle to maintain tension with comparatively less ATP consumption because each cross-bridge cycle uses up one molecule of ATP. Smooth muscle is therefore an economical contractile tissue, making it well suited for long-term sustained contractions with little energy consumption and without fatigue. In contrast to the rapidly changing demands placed on your skeletal muscles as you manoeuvre through and manipulate your external environment, your smooth muscle activities are geared for long-term duration and slower adjustments to change.

Because of its slowness and the less ordered arrangement of its filaments, smooth muscle has often been mistakenly viewed as a poorly developed version of skeletal muscle. Actually, smooth muscle is just as highly specialized for the demands

placed on it—that is, being able to economically maintain tension for prolonged periods without fatigue and being able to vary considerably in the volume of contents it holds, with little change in tension. It is an extremely adaptive, efficient tissue.

Nutrient and oxygen delivery are generally adequate to support the smooth muscle contractile process. Smooth muscle can use a wide variety of nutrient molecules for ATP production. There are no energy storage pools comparable to creatine phosphate in smooth muscle; they are not necessary. Oxygen delivery is usually adequate to keep pace with the low rate of oxidative phosphorylation needed to provide ATP for the energy-efficient smooth muscle. If necessary, anaerobic glycolysis can sustain adequate ATP production if oxygen supplies are diminished.

Cardiac muscle

Cardiac muscle functions differently from both skeletal and smooth muscle. Here we look briefly at these key differences so you can compare and contrast all three types of muscle cells. An in-depth discussion on cardiac muscle is included in the chapter on cardiac physiology (Chapter 8).

Cardiac muscle, found only in the heart, shares structural and functional characteristics with both skeletal and single-unit smooth muscle. Like skeletal muscle, cardiac muscle is striated, with its thick and thin filaments highly organized into a regular banding pattern. Cardiac thin filaments contain troponin and tropomyosin, which constitute the site of Ca^{2+} action in switching on cross-bridge activity, as in skeletal muscle. Also like skeletal muscle, cardiac muscle has a clear length-tension relationship. Like the oxidative skeletal muscle fibres, cardiac muscle cells have lots of mitochondria and myoglobin. They also have T tubules and a moderately well-developed SR.

As in smooth muscle, Ca^{2+} enters the cytosol from both the ECF and the SR during cardiac excitation. Ca^{2+} entry from the ECF occurs through voltage-gated calcium channels. This Ca^{2+} entry from the ECF triggers release of Ca^{2+} intracellularly from the SR. Like single-unit smooth muscle, the heart displays pacemaker (but not slow-wave) activity, initiating its own action potentials without any external influence. Cardiac cells are interconnected by gap junctions that enhance the spread of action potentials throughout the heart, just as in single-unit smooth muscle. Also, the heart is similarly innervated by the autonomic nervous system, which, along with certain hormones and local factors, can modify the rate and strength of contraction.

Unique to cardiac muscle, the cardiac fibres are joined in a branching network, and the action potentials of cardiac muscle last much longer before repolarizing. Further details and the importance of cardiac muscle's features are addressed in Chapter 8.

Chapter in Perspective: Focus on Homeostasis

Skeletal muscles compose the muscular system itself. Cardiac and smooth muscle are part of the organs that make up other body systems. Cardiac muscle is found only in the

heart, which is part of the circulatory system. Smooth muscle is found in the walls of hollow organs and tubes, including the blood vessels in the circulatory system, airways in the respiratory system, bladder in the urinary system, stomach and intestines in the digestive system, and uterus and ductus deferens (the duct through which sperm leave the testes) in the reproductive system.

Contraction of skeletal muscles accomplishes both the movement of body parts in relation to one another and also the movement of the whole body in relation to the external environment. Thus, these muscles permit you to move through and manipulate your external environment. At a very general level, some of these movements are aimed at maintaining homeostasis, such as moving the body toward food or away from harm. Examples of more specific homeostatic functions accomplished by skeletal muscles include chewing and swallowing food for further breakdown in the digestive system into usable energy-producing nutrient molecules (the mouth and throat

muscles are all skeletal muscles), and breathing to obtain oxygen and get rid of carbon dioxide (the respiratory muscles are all skeletal muscles). Heat generation by contracting skeletal muscles also is the major source of heat production in maintaining body temperature. The skeletal muscles further accomplish many nonhomeostatic activities that enable us to work and play—for example, operating a computer or riding a bicycle—so that we can contribute to society and enjoy ourselves.

All the other systems of the body, except the immune (defence) system, depend on their nonskeletal muscle components to enable them to accomplish their homeostatic functions. For example, contraction of cardiac muscle in the heart pushes life-sustaining blood forward into the blood vessels, and contraction of smooth muscle in the stomach and intestines pushes the ingested food through the digestive tract at a rate appropriate for the digestive juices secreted along the route to break down the food into usable units.

CHAPTER TERMINOLOGY

A band (p. 300)
actin (p. 301)
aerobic (endurance) exercise (p. 320)
alpha motor neurons (p. 325)
anaerobic (high-intensity) exercise (p. 320)
asynchronous recruitment of motor units (p. 310)
atrophy (p. 320)
calmodulin (p. 329)
cardiac muscle (p. 326)
central fatigue (p. 318)
concentric muscle contraction (p. 315)
contractile component (p. 313)
contractile proteins (p. 301)
contraction time (p. 308)
corticospinal (pyramidal) motor system (p. 323)
cross bridges (myosin heads) (p. 300)
denervation atrophy (p. 320)
dense bodies (p. 329)
dihydropyridine receptors (p. 305)
disuse atrophy (p. 320)
dystrophin (p. 322)
eccentric muscle contraction (p. 315)
endomysium (p. 298)
epimysium (p. 298)
excitation–contraction coupling (p. 303)
extrafusal fibres (p. 325)
fast-twitch fibres (p. 318)
fatigue (p. 310)
flaccid paralysis (p. 325)
foot proteins (p. 304)

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-42)

- On completion of an action potential in a muscle fibre, the contractile activity initiated by the action potential ceases. (*True or false?*)
- The velocity at which a muscle shortens depends entirely on the ATPase activity of its fibres. (*True or false?*)
- When a skeletal muscle is maximally stretched, it can develop maximal tension on contraction, because the actin filaments can slide in a maximal distance. (*True or false?*)
- A pacemaker potential always initiates an action potential. (*True or false?*)
- A slow-wave potential always initiates an action potential. (*True or false?*)
- Smooth muscle can develop tension even when considerably stretched, because the thin filaments still overlap with the long thick filaments. (*True or false?*)
- A(n) _____ contraction is an isotonic contraction in which the muscle shortens, whereas the muscle lengthens in a(n) _____ isotonic contraction.
- _____ motor neurons supply extrafusal muscle fibres, whereas intrafusal fibres are innervated by _____ motor neurons.
- The two types of atrophy are _____ and _____.
- Which of the following provide(s) direct input to alpha motor neurons? (Indicate all correct answers.)
 - primary motor cortex
 - brain stem
 - cerebellum
 - basal nuclei
 - spinal reflex pathways
- Which of the following is NOT involved in bringing about muscle relaxation?
 - reuptake of Ca^{2+} by the sarcoplasmic reticulum
 - no more ATP
 - no more action potential
 - removal of ACh at the end plate by acetylcholinesterase
 - filaments sliding back to their resting position

12. Match the following (with reference to skeletal muscle):

- | | |
|--|---|
| _____ 1. Ca^{2+} | (a) cyclically binds with the myosin cross bridges during contraction |
| _____ 2. T tubule | (b) has ATPase activity |
| _____ 3. ATP | (c) supplies energy for the power stroke of a cross bridge |
| _____ 4. lateral sac of the sarcoplasmic reticulum | (d) rapidly transmits the action potential to the central portion of the muscle fibre |
| _____ 5. myosin | (e) stores Ca^{2+} |
| _____ 6. troponin–tropomyosin complex | (f) pulls the troponin–tropomyosin complex out of its blocking position |
| _____ 7. actin | (g) prevents actin from interacting with myosin when the muscle fibre is not excited |

13. Using the answer code at the right, indicate what happens in the banding pattern during contraction:

- | | |
|----------------------------|---|
| _____ 1. thick myofilament | (a) remains the same size during contraction |
| _____ 2. thin myofilament | (b) decreases in length (shortens) during contraction |
| _____ 3. A band | |
| _____ 4. I band | |
| _____ 5. H zone | |
| _____ 6. sarcomere | |

Written Questions

- Describe the levels of organization in a skeletal muscle.
- What produces the striated appearance of skeletal muscles? Describe the arrangement of thick and thin filaments that gives rise to the banding pattern.
- What is the functional unit of skeletal muscle?
- Describe the composition of thick and thin filaments.
- Describe the sliding filament mechanism of muscle contraction. How do cross-bridge power strokes bring about shortening of the muscle fibre?

6. Compare the excitation–contraction coupling process in skeletal muscle with that in smooth muscle.
7. How can gradation of skeletal muscle contraction be accomplished?
8. What is a motor unit? Compare the size of motor units in finely controlled muscles with those specialized for coarse, powerful contractions. Describe motor unit recruitment.
9. Explain *twitch summation* and *tetanus*.
10. How does a skeletal muscle fibre's length at the onset of contraction affect the strength of the subsequent contraction?
11. Compare isotonic and isometric contractions.
12. Compare the three types of skeletal muscle fibres.
13. What are the roles of the corticospinal system and multi-neuronal system in controlling motor movement?
14. Describe the structure and function of muscle spindles and Golgi tendon organs.
15. Distinguish between multiunit and single-unit smooth muscle.
16. Differentiate between neurogenic and myogenic muscle activity.
17. How can smooth muscle contraction be graded?
18. Compare the contractile speed and relative energy expenditure of skeletal muscle with that of smooth muscle.
19. In what ways is cardiac muscle functionally similar to skeletal muscle and to single-unit smooth muscle?

Quantitative Exercises (Solutions in Appendix E, p. A-42)

1. Consider two individuals each throwing a baseball, one a weekend athlete and the other a professional pitcher.
 - a. Given the following information, calculate the velocity of the ball as it leaves the amateur's hand:

- The distance from his shoulder socket (humeral head) to the ball is 70 cm.
 - The distance from his humeral head to the points of insertion of the muscles moving his arm forward (we must simplify here, because the shoulder is such a complex joint) is 9 cm.
 - The velocity of muscle shortening is 2.6 m/sec.
- b. The professional pitcher throws the ball 137 km per hour. If his points of insertion are also 9 cm from the humeral head and the distance from his humeral head to the ball is 90 cm, how much faster did the professional pitcher's muscles shorten compared with the amateur's?

2. The velocity at which a muscle shortens is related to the force that it can generate in the following way:¹

$$v = b(F_0 - F)/(F + a)$$

where v is the velocity of shortening, and F_0 can be thought of as an “upper load limit,” or the maximum force a muscle can generate against a resistance. The parameter a is inversely proportional to the cross-bridge cycling rate, and b is proportional to the number of sarcomeres in line in a muscle. Draw the resistance (force)–velocity curve predicted by this equation by plotting the points $F = 0$ and $F = F_0$. Values of v are on the vertical axis; values of F are on the horizontal axis; a , b , and F_0 are constants.

- a. Notice that the curve generated from this equation is the same as that in Figure 7-20, p. 315. Why does the curve have this shape? That is, what does the shape of the curve tell you about muscle performance in general?
- b. What happens to the resistance (force)–velocity curve when F_0 is increased? When the cross-bridge cycling rate is increased? When the size of the muscle is increased? How will each of these changes affect the performance of the muscle?

¹F.C. Hoppensteadt & C.S. Peskin, *Mathematics in Medicine and the Life Sciences* (New York: Springer, 1992), equation 9.1.1, p. 199.

POINTS TO PONDER

(Explanations in Appendix E, p. A-43)

1. Why does regular aerobic exercise provide more cardiovascular benefit than weight training does? (*Hint*: The heart responds to the demands placed on it in a way similar to that of skeletal muscle.)
2. If the biceps muscle of a child inserts 4 cm from the elbow and the length of the arm from the elbow to the hand is 28 cm, how much force must the biceps generate in order for the child to lift an 8 kg stack of books with one hand?

3. Put yourself in the position of the scientists who discovered the sliding filament mechanism of muscle contraction, by considering what molecular changes must be involved to account for the observed alterations in the banding pattern during contraction. If you were comparing a relaxed and contracted muscle fibre under an electron microscope (see Figure 6-3a), how could you determine that the thin filaments do not change in length during muscle contraction? You cannot see or measure a single thin filament at this magnification. (*Hint*: What landmark in the banding pattern represents each end of the thin filament? If these

landmarks are the same distance apart in a relaxed and contracted fibre, then the thin filaments must not change in length.)

4. What type of off-the-snow training would you recommend for a competitive downhill skier versus a competitive cross-country skier? What adaptive skeletal muscle changes would you hope to accomplish in the athletes in each case?
5. When the bladder is filled and the micturition (urination) reflex is initiated, the nervous supply to the bladder promotes contraction of the bladder and relaxation of the

external urethral sphincter, a ring of muscle that guards the exit from the bladder. If the time is inopportune for bladder emptying when the micturition reflex is initiated, the external urethral sphincter can be voluntarily tightened to prevent urination even though the bladder is contracting. Using your knowledge of the muscle types and their innervation, of what types of muscle are the bladder and the external urethral sphincter composed, and what branch of the efferent division of the peripheral nervous system supplies each of these muscles?

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-43)

Jason W. is waiting impatiently for the doctor to finish removing the cast from his leg, which Jason broke the last day of school six weeks ago. Summer vacation is half over, and he hasn't been able to swim, play baseball, or participate in any of his favourite

sports. When the cast is finally off, Jason's excitement gives way to concern when he sees that the injured limb is noticeably smaller in diameter than his normal leg. What explains this reduction in size? How can the leg be restored to its normal size and functional ability?

Normal: Human Movement

Generally, *locomotion* is simply walking, jogging, or running. Locomotion addresses the body's ability to move (i.e., locomote) from place to place. Human locomotion is bipedal (having two legs and feet). It uses the oscillating contraction–relaxation of skeletal muscles in a coordinated manner which, as a result, allows one foot to be moved in front of the other. The locomotive muscle groups are those of the hip, knee, and ankle flexors and extensors. These muscle groups are used to walk, jog, run, and stand.

To examine locomotion, we need to first discuss the human *gait* and outline a *gait cycle*. By definition, *gait* is the rhythmic alternating movement of the legs resulting in the forward movement of the body. Gait has three phases: stance (single leg support of body weight), swing (unsupported), and double support (standing). A gait cycle is the activity that takes place between heel strike of one limb and the successive heel strike of the same limb. The analysis of gait is often discussed in terms of the following components: (1) heel strike, (2) mid-stance, (3) toe off, and (4) acceleration. Many different factors influence each of these components (e.g., how much knee flexion and hip extension a person uses). Individuals have a unique characteristic gait—their gait pattern. For example, during heel strike, does the foot contact the ground more toward the heel or midfoot? For further discussion on variation and evolution in gait patterns and their relationship to running shoes and injury, Dr. Daniel Lieberman from Harvard has written some interesting articles on the topic (e.g., [2010, Jan. 28]. Foot strike patterns and collision forces in habitually barefoot versus shod runners. *Nature*, 463[7280]: 531–5; [2004, Nov 18]. Endurance running and the evolution of Homo. *Nature*, 432[7015]: 345–52). Although there is variation with each person's gait, generally all gait cycles can be broken down into the phases and components we just described. So, what controls gait and allows locomotion to occur in a smooth reflexive manner?

Several physiological components are required to accomplish locomotion. First we focus on the *control* of locomotion, which is the responsibility of the central and peripheral nervous systems (CNS and PNS; see Chapters 3 and 4). Then we discuss how skeletal muscle contractions (concentric and eccentric) enable external motion to occur.

Locomotion is executed for the most part without input from higher brain centres and requires no conscious control. Instead, the body uses learned motor programs (patterns) stored in groups of neurons in the spinal cord and brain stem; these are termed *central pattern generators* (CPGs).

Furthermore, information from a variety of peripheral sensory receptors (e.g., muscle spindles) provides feedback to the CPGs to confirm the movement patterns and assist with corrective actions when necessary. Both afferent (sensory) and efferent

(motor) neurons are needed, as well as ascending (sensory) and descending (motor) spinal pathways. Of greatest interest are the CPGs, sensory receptors, and descending motor pathways.

Central Pattern Generators

Locomotion is complex, as there are both limb movements (e.g., leg) and segmental movements (e.g., movement of the calf independent of the thigh) that need to be coordinated during walking and running. Although sensory feedback and the mechanical properties of the musculoskeletal system contribute to this coordination, it is important to realize that the rhythms and patterns arise from the spine and brain stem (i.e., CPGs).

The body uses various CPGs to control many processes aside from locomotion—for example, breathing, chewing, and posture. CPGs are neural networks, located in both the spine and brain stem, that can produce rhythmic outputs without supraspinal input, and that bring about most rhythmic motor (movement) patterns. This suggests that rhythmic pattern generation does not rely on the entire nervous system functioning as a whole, but rather depends on smaller sections of the nervous system functioning as autonomic (automatic) neural networks. Sensory (afferent) input to the CPGs is used to make quick and complex decisions regarding repetitive movements such as when environmental changes (e.g., a change in walking surfaces—flat to uneven) are encountered.

The automatic nature of the CPGs is not fully understood, but it is believed that automaticity makes locomotion easier because the locomotive nerves (afferent and efferent) and skeletal muscles form a collective interactive system—that is, all components are interdependent. Motor pools are an example of this concept of grouping. Motor pools consist of all the motor neurons that innervate the muscle fibres within the same whole muscle. Within a motor pool there are different sizes and types of motor neurons randomly distributed within the muscle. This may seem complex, but this organization makes locomotion easier than it would be if the CNS had to coordinate each individual motor axon and muscle fibre separately. By grouping the nerves and muscles into systems, it allows the control of the movement patterns to be simplified, made formulaic, varying only in speed of movement or until sensory or supraspinal input regarding the environment (e.g., uneven surfaces) indicates an adjustment is required.

The spinal cord also interprets incoming sensory information to make the necessary adjustments in the locomotive pattern, adjusting the gait cycle. The spinal cord interprets the sensory information from all aspects of the gait during locomotion—for example, foot contact, force, changes in joint angle and acceleration—and predicts which groups of neurons (i.e., systems) to activate and which to inhibit to allow movement to continue or stop. Thus, to make adjustments in gait, sensory input from peripheral afferent receptors is paramount.

Peripheral Sensors

The sensory receptors used in locomotion are located peripherally, and referred to as *mechanoreceptors* (see Chapter 4); they sense physiological and mechanical changes and send the information to the spinal cord for processing. Muscle spindles, Golgi tendon organs (GTOs), and free nerve endings provide much of the sensory information for *proprioception* associated with locomotion. Mechanoreceptors are located in the skeletal muscles, tendons, and joints, and provide the spinal cord with information regarding limb position and movement (kinematics). About half of the nerves in the skeletal muscle system are sensory; this provides a great deal of feedback to the CNS. To give some perspective, it is estimated that one large afferent neuron could provide in excess of 8 billion action potentials (APs) per second. Some mechanoreceptors sense force and pressure, but we will focus on the muscle spindles, which sense change in muscle fibre length.

Muscle Spindles

Muscle spindles (see Chapter 7) contain striated muscle (i.e., intrafusal fibres) similar to those of the extrafusal fibres (i.e., skeletal muscle). The muscle spindle is surrounded by a collagen sheath that holds the contents collectively as a unit. The intrafusal fibres are innervated by γ -motor neurons (efferent) as well as sensory afferent neurons (primary and secondary). The sensory neurons generate APs that are sent to the spine when there is even a minute change in length of the intrafusal fibres; with respect to locomotion it is the primary afferent that is most important (i.e., Ia). The sensory neurons respond to passive change in length of the intrafusal fibres. This change in length is brought about by a change in length of the skeletal muscle fibres, as the extrafusal fibres and intrafusal fibres run in parallel to each other.

During locomotion, the muscle spindles send sensory input to the spine, thereby providing information about changes in fibre length as the muscles move through their normal range of motion associated with the gait cycle. So as the leg swings forward, the quadriceps muscle begins to concentrically contract (shorten) as it readies to plant (heel strike) for the stance phase and bear the weight of the body. The muscle spindles monitor both the change in length and the rate of change of the quadriceps muscle millisecond by millisecond, as well as all other muscles associated with locomotion.

Locomotion

During walking, the muscle spindles of the lower limb musculature (e.g., quadriceps) are continuously activated, whether the leg is planted during stance phase or in the air during swing phase. It is irrelevant whether the skeletal muscles are eccentrically or concentrically contracting; the muscle spindles are activated because there is a change in length within the skeletal muscles and thus within the muscle spindles.

This muscle activity or activation pattern can be measured by electromyography (EMG), which senses the electrical activity (both the frequency and amplitude) of muscles. An interesting characteristic of muscle activation identified by EMG is that

the γ -motor and α -motor neurons activation patterns differ not only from muscle fibre to fibre, but also from step to step within the same muscle fibres. This provides a clue as to the complexity of the nervous signalling from the periphery to the spinal cord, which interprets and responds to the physiological and mechanical stimuli provided by the spindles from step to step, millisecond to millisecond.

In practical terms, the muscle spindles sense where the stance phase and swing phase of walking (or running) should begin and end. As the swing phase ends, the stance phase must begin, and thus the weight of the body must be supported. As the body weight is carried, it is sensed by the GTOs and free nerve endings to provide feedback on joint angle and the level of force needed to support the body weight. This is important for a smooth transition from swing phases to stance in the gait cycle, because it permits a smooth locomotion that is characteristic in the healthy human.

It should be noted that the GTOs, contrary to popular belief, are not simply a safety mechanism used to inhibit skeletal muscles when the muscular force generated is too great. The sensory information gathered by the GTOs is used to inhibit specific muscles during a normal walking gate, even when the forces within the muscles are relatively low. Additionally, free nerve endings are used to gather sensory information regarding mechanical stimuli such as touch, pressure, and stretch, and sends the information (e.g., sensing joint angle) to the spinal cord.

The muscle spindles, GTOs, and free nerve endings provide a wealth of proprioceptive information to the spine for incorporation and interpretation by the CPGs. It is proposed that the spine treats this incoming information as a *recognizable pattern* and compares it to known templates for locomotion. Remember, this is how we get the automaticity demonstrated by the spine (CPGs) during walking. This information is used to predictably adjust the kinematics of walking and running, which reduces the need for supraspinal input and thus conscious control.

Supraspinal Control

As discussed, much of locomotion is directed by automaticity in the neurons associated with the CPGs of the spine and brain stem. However, evidence suggests that the *initiation and gross adjustments* of locomotion are via the supraspinal centre, the motor cortex (divisions: primary motor cortex, posterior parietal cortex, supplementary motor area, and premotor cortex). Additionally, the motor cortex is important for executing *nonrepetitive* skilled movement patterns and adjusting activation patterns of efferent motor output in unusual environments (e.g., running on uneven ground, cross-country running).

The supraspinal descending pathways used for locomotion are the reticulospinal, corticospinal, rubrospinal, and vestibulospinal tracts, which are efferent motor pathways that activate the skeletal muscles for the purposes of locomotion (among other things). Each region varies in level of activity depending on the phase of gait (e.g., swing, stance). It is fair to say that without the spinal tracts, particularly the reticulospinal tract, it is doubtful that locomotion as we know it (coordinated, smooth, modifiable, etc.) could take place.

The reticulospinal tract is formed by neuronal fibres originating in the pons and medulla (brain stem) and that descend through the spinal cord to innervate motor neurons. The cerebellum receives input from the reticulospinal tract and is vital for adjusting supraspinal input, modulating sensory feedback from the spinal cord, and adapting motor output based on need. The cerebellum also receives input from CPGs to assist in modulating motor output to the locomotor muscles. The reticulospinal tract takes the input from the brain stem, and the modulated output from the cerebellum, and continues to descend the spine to transfer the information to the locomotor muscles.

Consequently, the brain stem and cerebellum allow for unplanned modifications in locomotion such as occur for example when we encounter unforeseen objects or slippery surfaces. The combined functioning of the motor cortex, brain stem, and cerebellum enable us to plan for anticipated changes in our immediate environment that require a response. For example, when we are standing in a subway car, it is important that the motor cortex plans for the car slowing down at the next subway stop. In this case, the motor cortex initiates the transition of our body weight toward the direction opposite from where the car is moving, thereby offsetting the forward movement. Simultaneously, the brain stem and cerebellum compare the plan initiated by the motor cortex and the sensory feedback from the peripheral receptors and assess the need for adjustment: that is, did the initiated pattern match what happened? Adjustments may take place if the subway car driver stops the car at a faster rate than we anticipated, and thus our lean toward the rear of the car may need to be greater than anticipated by the motor cortex's initial plan.

When broken down into its component parts, locomotion could be seen as a complex task; in fact, it is facilitated by (1) having a lot of sensory input from a variety of sensors, (2) using motor patterns or templates for comparison, (3) grouping the neural activity into smaller systems, (4) having CPGs in the spine and brain stem make fast adjustments in neural output based on the sensory input, and (5) having automaticity so that the general process of walking and all necessary adjustments do not need to reach conscious awareness. All of these contributions reduce the need to actively think about each step of walking and running.

We take much of this integration for granted. But what happens when things go wrong? For example, what is the outcome when disease begins to disrupt the neural networking and communication between the brain, spinal cord, and skeletal muscles? We now examine abnormal function brought on by disease.

Abnormal: Parkinson's Disease

One afternoon, 38-year-old JH sat down to read a book. After a while he noticed that both his left index finger and thumb had a slight tremor. Upon reflection, he realized that this had been going on for a month or so. Since he worked on a computer all day and was constantly texting friends and family, he thought that perhaps it was just that his fingers were stressed from constantly being in motion. A few months later, more of his fingers would now twitch on occasion and some of his toes had started

as well. He started reading about these symptoms on the Internet and decided that he should see his family physician. Two weeks later, JH was diagnosed with *Parkinson's disease*.

Parkinson's disease is a neurodegenerative disorder that has no cure. The early symptoms of Parkinson's disease are usually movement-related and manifest primarily as tremors at rest. As the disease progresses, these movement disorders worsen and can include slowness of movement, rigidity, impaired balance, and difficulty with walking. However, in addition to movement disorders, Parkinson's disease is also associated with several other symptoms such as cognitive disorders and dementia, behavioural problems, altered senses, and sleep disturbances.

Parkinson's disease is clearly a complex disease that can affect several of the body's systems. In this section, we examine the changes that occur in the central nervous system and how this affects the signals that are sent to other regions of the brain and the rest of the body. While we focus primarily on the integrative aspect of movement control, we also discuss the integrative nature of the non-movement symptoms as well.

What Is the Cause of Parkinson's Disease?

In general, Parkinson's disease is considered to be *idiopathic*, which means there is no known cause. There is, however, a genetic link for some people and mutations in several genes can lead to the disease. Regardless of the cause, research has identified the changes that occur within the central nervous system that ultimately lead to the symptoms of the disease.

The region of the brain most affected by Parkinson's disease is within the *basal ganglia*. As the word *ganglia* suggests, the basal ganglia actually consists of several structures, including the caudate nucleus, the globus pallidus, the putamen, the subthalamic nucleus, and the *substantia nigra*. Altogether, the basal ganglia is associated with many functions, including movement, attention, and learning, so it is not surprising that alterations within these regions underlie the symptoms of Parkinson's disease.

That said, not all of these basal ganglia structures are involved. The primary symptoms of Parkinson's disease are caused by the death of dopamine-secreting neurons within the *substantia nigra pars compacta*. However, what causes these neurons to die is unknown. One of the leading theories is that, for some reason, these cells begin to produce too much of a protein called *alpha-synuclein*. This protein is not soluble and aggregates to form what are called *Lewy bodies*. It is unknown if these Lewy bodies themselves can kill neurons. Along with the Lewy bodies, iron can be concentrated, and it is thought that perhaps this excessive iron causes oxidative stress that ultimately lead to cell death.

How Does This Affect Movement?

The control of any body system is complex and highly regulated not only to maintain homeostasis but also to respond appropriately to changes within the body or the environment. Conceptually,

most systems have stimulatory and inhibitory inputs (antagonistic control), and it is the relative level of these inputs that determines the activity of a particular system. If the body needs to increase the function of a system, it can either increase the stimulatory inputs or decrease the inhibitory inputs. To decrease function, the opposite may occur. You will see this concept repeated throughout the textbook as it applies to specific systems.

This concept of control can also be applied to the control of movement. As you learned in Chapter 3, the motor division of the peripheral nervous system is composed of the autonomic nervous system, for involuntary control, and the somatic nervous system, for voluntary control. Of these, the somatic nervous system has control over skeletal muscle. In the periphery, motor neurons extend from the spinal cord to innervate muscle cells. Motor neurons themselves can only stimulate these muscle cells, so they need to be able to regulate the rate at which they fire to control contraction and, thus, movement. This regulation is accomplished by balancing the stimulatory and inhibitory inputs to the dendrites of motor neurons. Therefore, the summation of these inputs determines the relative activity of the muscle neurons.

This balance of input has three levels of control regulated by the spinal cord, the brain stem, and the primary motor cortex. Spinal cord control is responsible primarily for reflexes and rhythmic movements, whereas the brain stem and higher brain centres are responsible for voluntary movement. Afferent fibres from the primary motor cortex descend to terminate on motor neurons (or regulatory interneurons) in the spinal cord. The brain stem also projects to motor neurons but serves as a processing centre and receives input from the cerebellum, premotor cortex, and the basal ganglia. Altogether, this complex regulation of movement allows for precise movements of voluntary skeletal muscles throughout the body. However, such complexity also permits diseases that affect specific brain areas, such as Parkinson's disease, to throw this modulation of movement out of balance.

The exact role that the substantia nigra pars compacta plays in movement is not fully understood. It has been shown that direct electrical stimulation of this brain region does not result in movement. However, decreased function of these neurons, as seen in Parkinson's disease, does have an effect on movement, in particular, fine motor control.

The pars compacta receives input primarily from the caudate and putamen. Because it uses dopamine as a neurotransmitter, the pars compacta's output is considered inhibitory; this output projects back to the caudate and putamen, which in turn project to the thalamus and the cortex. Under normal circumstances, this inhibitory output is considered one of the many factors that suppress movement. This is most notable when a muscle is at rest because the inhibitory pathways then dominate the control of movement.

People with Parkinson's disease begin to lose this inhibitory output on movement, so the balance of movement control is disrupted, which unmasks the underlying stimulatory pathways. The net consequence is the occurrence of resting tremors commonly associated with this disease. In the early stages, these tremors can be masked or overridden by voluntary movement. As the disease progresses, however, tremors can appear on top of voluntary movements. The later stages of the disease are also characterized by *rigidity* of movement—both flexors and extensors are simultaneously stimulated—and *bradykinesia* (slow movement) because it becomes difficult to initiate voluntary movement.

Non-movement Symptoms of Parkinson's Disease

Parkinson's disease is frequently considered a disease of movement, but this is certainly not the case. Given the complex organization of the brain, it should be of no surprise that Parkinson's disease also affects behaviour, mood, and cognition. Some of the other observed symptoms include anxiety, depression, behavioural changes, sleep disturbances, and dementia.

It is estimated that more than 50 percent of persons with Parkinson's disease have some form of cognitive impairment ranging from mild to *dementia*. The precise mechanisms by which this occurs is unclear, but there are similarities with a well-known dementia disease, Alzheimer's. In both Parkinson's and Alzheimer's, there is a progressive loss of memory, reasoning, and language. That said, the dementia associated with Parkinson's disease is more likely associated with the second most common form of dementia, *Lewy Body Dementia*. As already mentioned, the aggregation of alpha-synuclein leads to the presence of Lewy bodies, which is a progressive degradation of cholinergic neurons associated with cognition. However, both the role of Lewy bodies in the progressive degradation of dopaminergic neurons in the substantia nigra, and also the way that Lewy bodies contribute to cholinergic cell death remain unclear.

Integrated Control of Movement

The purpose of this section has been to highlight the integrative nature of movement. Control of movement involves multiple steps from the initiation of movement in the primary motor cortex to the peripheral grouping of neurons (motor pools), which ultimately leads to precise skeletal muscle control and locomotion. Within this cascade of events, there are many means by which movement can be modulated. In this particular case, we used Parkinson's disease as an example of such modulation. As such, we demonstrated that the removal of one of the pathways that endogenously suppresses movement can drastically disrupt the balance of control and cause a deleterious movement disorder.

Cardiac Physiology

Body systems maintain homeostasis

Human vascular system

Cells make up body systems

Homeostasis

The circulatory system contributes to homeostasis by transporting O_2 , CO_2 , wastes, electrolytes, and hormones from one part of the body to another.

Homeostasis is essential for survival of cells

Heart valves

Med-Mation Ltd/Science Source

The maintenance of homeostasis depends on essential materials, such as oxygen and nutrients, being continually picked up from the external environment and delivered to the cells and on waste products being continually removed. Furthermore, excess heat generated by muscles must be transported to the skin where it can be lost from the body surface to help maintain body temperature. Homeostasis also depends on the transfer of hormones, which are important regulatory chemical messengers, from

their site of production to their site of action. The circulatory system, which contributes to homeostasis by serving as the body's transport system, consists of the heart, blood vessels, and blood.

All body tissues constantly depend on the life-supporting blood flow the heart provides them by contracting, or beating. The heart drives blood through the blood vessels for delivery to the tissues in sufficient amounts, whether the body is at rest or engaging in vigorous exercise.

Clinical Connections

Debbie arrived home after a long day at work and, feeling more tired than usual, sat down to relax for a few minutes. Suddenly, she felt very strange and started to feel an almost crushing pressure on her chest. She started sweating and felt as if she was unable to catch her breath. Her spouse immediately called 911, and within 40 minutes she was in the hospital emergency room.

On arrival, her electrocardiogram showed ST elevation, and she was immediately given a thrombolytic. She remained conscious, and the severity of her symptoms improved. Blood taken about two hours after her arrival showed elevated myoglobin. Subsequent blood samples also had elevated levels of troponin T. After undergoing an angiogram that showed an almost complete blockage of her left main coronary artery, she was immediately sent to surgery for a coronary artery bypass graft. Debbie had an acute myocardial infarction.

8.1 | Introduction

From just a matter of days following conception until death, the beat goes on. In fact, throughout an average human lifespan, the heart contracts about 3 billion times, never stopping except for a fraction of a second to fill between beats. Within the developing embryo, the heart is the first organ to become functional, which occurs about three

weeks after conception. At this time, the human embryo is only a few millimetres long, about the size of a capital letter on this page.

Why does the heart develop so early, and why is it so crucial throughout life? It is this important because the circulatory system is the body's transport system. A human embryo, having very little yolk available as food, depends on promptly establishing a circulatory system that can interact with the mother's circulation to pick up and distribute to the developing tissues the supplies so critical for survival and growth. Thus begins the story of the circulatory system, which continues throughout life to be a vital pipeline for transporting materials on which the cells of the body absolutely depend.

The **circulatory system** has three basic components:

1. The **heart** serves as the pump that imparts pressure to the blood to establish the pressure gradient needed for blood to flow to the tissues. Like all liquids, blood flows down a pressure gradient from an area of higher pressure to an area of lower pressure. This chapter focuses on cardiac physiology (*cardia* means “heart”).
2. The **blood vessels** serve as the passageways through which blood is directed and distributed from the heart to all parts of the body and subsequently returned to the heart (see Chapter 9).
3. **Blood** is the transport medium within which materials being moved long distances in the body (such as oxygen, carbon dioxide, nutrients, wastes, electrolytes, and hormones) are dissolved or suspended (see Chapter 10).

Blood travels continuously through the circulatory system to and from the heart through two separate vascular (blood vessel) loops, both originating and terminating at the heart (► Figure 8-1). The **pulmonary circulation** consists of a closed loop of vessels carrying blood between the heart and lungs (*pulmo* means “lung”). The **systemic circulation** is a circuit of vessels carrying blood between the heart and other body systems.

8.2 | Anatomy of the Heart

The heart is a hollow, muscular organ about the size of a clenched fist. It lies in the **thoracic cavity** (chest) at about the midline, in between the **sternum** (breastbone) anteriorly and the **vertebrae** (backbone) posteriorly. Place your hand over your heart. People usually put their hand on the left side of the chest, even though the heart is actually in the middle of the chest. The heart has a broad **base** at the top and tapers to a pointed tip, the **apex**, at the bottom. It is situated at an angle under the sternum so that its base lies predominantly to the right and the apex to the left of the sternum. When the heart beats forcefully, the apex actually thumps against the inside of the chest wall on the left side. Because we become aware of the beating heart through the apex beat on the left side of the chest, we tend to think the entire heart is on the left.

► **FIGURE 8-1** Pulmonary and systemic circulation in relation to the heart. The circulatory system consists of two separate vascular loops: the pulmonary circulation, which carries blood between the heart and lungs; and the systemic circulation, which carries blood between the heart and organ systems.

A dual pump

Even though anatomically the heart is a single organ, the right and left sides of the heart function as two separate pumps. The heart is divided into right and left halves and has four chambers: an upper and a lower chamber within each half (► Figure 8-2a). The upper chambers, the **atria** (singular, *atrium*), receive blood returning to the heart and transfer it to the lower chambers, the **ventricles**, which pump blood from the heart. The vessels that return blood from the tissues to the atria are **veins**, and those that carry blood away from the ventricles to the tissues are **arteries**. The two halves of the heart are separated by the **septum**, a continuous muscular partition that prevents mixture of blood from the two sides of the heart. This separation is extremely

The heart's position between two bony structures, the sternum and vertebrae, makes it possible to manually drive blood out of the heart when it is not pumping effectively; this is done by rhythmically depressing the sternum. This manoeuvre compresses the heart between the sternum and vertebrae so that blood is squeezed out

into the blood vessels, maintaining blood flow to the tissues. Often, this *external cardiac compression*, which is part of **cardiopulmonary resuscitation (CPR)**, serves as a lifesaving measure until appropriate therapy can restore the heart to normal function.

important, because the right half of the heart is receiving and pumping oxygen-poor blood, whereas the left side of the heart receives and pumps oxygen-rich blood.

THE COMPLETE CIRCUIT OF BLOOD FLOW

Let us look at how the heart functions as a dual pump, by tracing a drop of blood through one complete circuit (► Figure 8-2a and ► 8-2b). Blood returning from the systemic circulation enters the right atrium via two large veins, the **venae cavae**: one returns blood from above heart level, and the other returns blood from below. The drop of blood entering the right atrium has returned from the body tissues, where oxygen has been taken from it and carbon dioxide has been added to it. This partially deoxygenated blood flows from the right atrium into the right ventricle, which pumps it out through the **pulmonary artery**. As the pulmonary artery leaves the right ventricle, it immediately forms two branches, one going to each of the two lungs. Thus, the *right side of the heart receives blood from the systemic circulation and pumps it into the pulmonary circulation*.

Within the lungs, the drop of blood loses its extra carbon dioxide and picks up a fresh supply of oxygen before being returned to the left atrium via the **pulmonary veins** coming from both lungs. This oxygen-rich blood returning to the left atrium subsequently flows into the *left ventricle, the pumping chamber that propels the blood to all body systems; that is, the left side of the heart receives blood from the pulmonary circulation and pumps it into the systemic circulation*. The single large artery carrying blood away from the left ventricle is the **aorta**. Major arteries branch from the aorta to supply the various organs of the body.

In contrast to the pulmonary circulation, in which all the blood flows through the lungs, the systemic circulation may be viewed as a series of parallel pathways. Part of the blood pumped out by the left ventricle goes to the muscles, part to the kidneys, part to the brain, and so on (Figure 8-2b). In this way, the output of the left ventricle is distributed so that each part of the body receives a fresh blood supply; the same arterial blood does not pass from organ to organ. Accordingly, the drop of blood we are tracing goes to only one of the systemic organs. Tissue cells within the organ take oxygen from the blood and use it to oxidize nutrients for energy production; in the process, the tissue cells form carbon dioxide as a waste product that is added to the blood. The drop of blood, now partially depleted of oxygen and

increased in carbon dioxide, returns to the right side of the heart, which once again pumps it to the lungs. One circuit is complete.

COMPARISON OF THE RIGHT AND LEFT PUMPS

A critical concept is that, despite being described as two separate pumps, both sides of the heart simultaneously pump equal amounts of blood. The volume of oxygen-poor blood being pumped to the lungs by the right side of the heart soon becomes the same volume of oxygen-rich blood being delivered to the tissues by the left side of the heart. The pulmonary circulation is a low-pressure, low-resistance system, whereas the systemic circulation is a high-pressure, high-resistance system. Within the circulatory system, pressure is the force exerted on the vessel walls by the blood pumped into the vessels by the heart. Resistance is the opposition to blood flow, largely caused by friction between the flowing blood and the vessel wall. Even though the right and left sides of the heart pump the same amount of blood, the left side performs more work, because it pumps an equal volume of blood at a higher pressure into a higher-resistance and longer system. Accordingly, the heart muscle on the left side is much thicker than the muscle on the right side, making the left side a stronger pump (► Figure 8-2c).

Pressure-operated heart valves

Blood flows through the heart in one fixed direction from veins to atria to ventricles to arteries. The presence of four one-way heart valves ensures this unidirectional flow of blood. The valves are positioned so that they open and close passively because of pressure differences, similar to a one-way door (► Figure 8-3). A forward pressure gradient (i.e., a greater pressure behind the valve) forces the valve open, much as you open a door by pushing on one side of it, whereas a backward pressure gradient (i.e., a greater pressure in front of the valve) forces the valve closed, just as you apply pressure to the opposite side of the door to close it. Note that a backward gradient can force the valve closed but cannot force it to swing open in the opposite direction; that is, heart valves are not like swinging, saloon-type doors.

AV VALVES BETWEEN THE ATRIA AND VENTRICLES

Two of the heart valves, the **right and left atrioventricular (AV) valves**, are positioned between the atrium and the ventricle on the right and left sides, respectively (► Figure 8-4a). These valves

FIGURE 8-2 Blood flow through and pump action of the heart. (a) Blood flow through the heart. (b) Dual pump action of the heart. The right side of the heart receives O₂-poor blood from the systemic circulation and pumps it into the pulmonary circulation. The left side of the heart receives O₂-rich blood from the pulmonary circulation and pumps it into the systemic circulation. Note the parallel pathways of blood flow through the systemic organs. (The relative volume of blood flowing through each organ is not drawn to scale.) (c) Comparison of the thickness of the right and left ventricular walls. Note that the left ventricular wall is much thicker than the right wall.

let blood flow from the atria into the ventricles during ventricular filling (when atrial pressure exceeds ventricular pressure) but prevent the backflow of blood from the ventricles into the atria during ventricular emptying (when ventricular pressure

greatly exceeds atrial pressure). If the rising ventricular pressure did not force the AV valves to close as the ventricles contracted to empty, much of the blood would inefficiently be forced back into the atria and veins instead of being pumped into the

► FIGURE 8-3 Mechanism of valve action

► FIGURE 8-4 Heart valves.

(a) Longitudinal section of the heart, depicting the location of the four heart valves. (b) The heart valves in closed position, viewed from above. (c) Prevention of eversion of the AV valves. Eversion of the AV valves is prevented by tension on the valve leaflets exerted by the chordae tendineae when the papillary muscles contract. (d) Prevention of eversion of the semilunar valves. When the semilunar valves are swept closed, their upturned edges fit together in a deep, leak-proof seam that prevents valve eversion.

from the inner surface of the ventricular walls (*papilla* means “nipple”). When the ventricles contract, the papillary muscles also contract, pulling downward on the chordae tendineae. This pulling exerts tension on the closed AV valve cusps and holds them in position, much like tethering ropes hold down a hot-air balloon. This action helps keep the valve tightly sealed in the face of a strong backward pressure gradient (► Figure 8-4c).

SEMILUNAR VALVES BETWEEN THE VENTRICLES AND MAJOR ARTERIES

The two remaining heart valves, the **aortic valve** and **pulmonary valve**, lie at the juncture where the major arteries leave the ventricles (Figure 8-4a). They are known as **semilunar valves** because they have three cusps, each resembling a shallow half-moon-shaped pocket (*semi* means “half”; *lunar* means “moon”) (Figure 8-4b). These valves are forced open when the left and right ventricular pressures exceed the pressure in the aorta and pulmonary artery, respectively, during ventricular contraction and emptying. Closure results when the ventricles relax and ventricular pressures fall below the aortic and pulmonary artery pressures. The closed valves prevent blood from flowing from the arteries back into the ventricles from which it has just been pumped.

The semilunar valves are prevented from everting by the anatomic structure and positioning of the cusps. During ventricular relaxation a backward pressure gradient is created, the back surge of blood fills the pocket-like cusps and sweeps them into a closed position, with their unattached upturned edges fitting together in a deep, leak-proof seam (► Figure 8-4d).

NO VALVES BETWEEN THE ATRIA AND VEINS

Even though there are no valves between the atria and veins, backflow of blood from the atria into the veins usually is not a significant problem, for two reasons: (1) atrial pressures usually are not much higher than venous pressures, and (2) the sites where the venae cavae enter the atria are partially compressed during atrial contraction.

FIBROUS SKELETON OF THE VALVES

Four interconnecting rings of dense connective tissue provide a firm base for attachment of the four heart valves (► Figure 8-5). This **fibrous skeleton**, which separates the atria from the ventricles, also provides a fairly rigid structure for attachment of the cardiac muscle. The atrial muscle mass is anchored above the rings, and the ventricular muscle mass is attached to the bottom of the rings.

It might seem rather surprising that the inlet valves to the ventricles (the AV valves) and the outlet valves from the ventricles (the semilunar valves) all lie on the same plane through the heart, as delineated by the fibrous skeleton. This relationship comes about because the heart forms from a single tube that bends on itself and twists on its axis during embryonic development. Although this turning and twisting make studying the structural relationships of the heart more difficult, the twisted structure has functional importance in that it helps the heart pump more efficiently. We will see how this happens by examining the portion of the heart that actually generates the forces responsible for blood flow: the cardiac muscle within the heart walls.

► **FIGURE 8-5 Fibrous skeleton of the heart.** A view of the heart from above, with the atria and major vessels removed to show the heart valves and fibrous rings. Note that the inlet and outlet valves to the ventricles all lie on the same plane through the heart.

The heart walls

The heart wall has three distinct layers:

- A thin inner layer, the **endothelium**, a unique type of epithelial tissue that lines the entire circulatory system
- A middle layer, the **myocardium**, which is composed of cardiac muscle and constitutes the bulk of the heart wall (*myo* means “muscle”; *cardia* means “heart”)
- A thin external layer, the **epicardium**, that covers the heart (*epi* means “on”)

The myocardium consists of interlacing bundles of cardiac muscle fibres arranged spirally around the circumference of the heart. The spiral arrangement is due to the heart’s complex twisting during development. As a result of this arrangement, when the ventricular muscle contracts and shortens, the diameter of the ventricular chambers is reduced while the apex is simultaneously pulled upward toward the top of the heart in a rotating manner. This motion squeezes the heart, which efficiently exerts pressure on the blood within the enclosed chambers and directs it upward toward the openings of the major arteries that exit at the base of the ventricles.

Cardiac muscle fibres

The individual cardiac muscle cells are interconnected to form branching fibres, with adjacent cells joined end to end at specialized structures known as **intercalated discs**. Within an intercalated disc, there are two types of membrane junctions: desmosomes and gap junctions (► Figure 8-6). A *desmosome*, a type of adhering junction that mechanically holds cells together, is particularly abundant in tissues, such as the heart, that are subject to considerable mechanical stress (p. 34). At intervals along the intercalated disc, the opposing membranes approach each other very closely to form *gap junctions*, which are areas of low electrical resistance that allow

(a) Bundles of cardiac muscle are arranged spirally around the ventricle. When they contract, they “wring” blood from the apex to the base where the major arteries exit.

Intercalated discs

(b) Cardiac muscle fibres branch and are interconnected by intercalated discs.

(c) Intercalated discs contain two types of membrane junctions: mechanically important desmosomes and electrically important gap junctions.

FIGURE 8-6 Organization of cardiac muscle fibres. Bundles of cardiac muscle fibres are arranged spirally around the ventricle. Adjacent cardiac muscle cells are joined end to end by intercalated discs, which contain two types of specialized junctions: desmosomes, which act as spot rivets mechanically holding the cells together; and gap junctions, which permit action potentials to spread from one cell to adjacent cells.

action potentials to spread from one cardiac cell to adjacent cells (p. 35). Some cardiac muscle cells can generate action potentials without any nervous stimulation. When one such cardiac cell spontaneously undergoes an action potential, the electrical impulse spreads to all the other cells that are joined by gap junctions in the surrounding muscle mass, so that they become excited and contract as a single, *functional syncytium* (p. 328). The atria and the ventricles each form a *functional syncytium* and contract as separate units. The synchronous contraction of the muscle cells that make up the walls of each of these chambers produces the pressure needed to eject the enclosed blood.

No gap junctions join the atrial and ventricular contractile cells, and, furthermore, the atria and ventricles are separated by the electrically nonconductive fibrous skeleton that surrounds and supports the valves. However, an important, specialized conduction system facilitates and coordinates transmission of electrical excitation from the atria to the ventricles to ensure synchronization between atrial and ventricular pumping.

Because of both the syncytial nature of cardiac muscle and the conduction system between the atria and ventricles, an impulse spontaneously generated in one part of the heart spreads throughout the entire heart. Therefore, unlike skeletal muscle, where graded contractions can be produced by varying the number of muscle cells contracting within the muscle (recruitment of motor units), either all the cardiac muscle fibres contract or none do. That said, cardiac contraction may be graded by varying the strength of contraction of all the cardiac muscle cells. You will learn more about this process later in Section 8.5.

The pericardial sac

The heart is enclosed in the double-walled, membranous **pericardial sac** (*peri* means “around”). The sac consists of two layers: a tough, fibrous covering and a secretory lining. The outer fibrous covering of the sac attaches to the connective tissue partition that separates the lungs. This attachment anchors the heart so that it remains properly positioned within the chest. The sac’s secretory lining secretes a thin **pericardial fluid**, which provides lubrication to prevent friction between the pericardial layers as they glide over each other with every beat of the heart.

Clinical Note **Pericarditis**, an inflammation of the pericardial sac that results in a painful friction rub between the two pericardial layers, occurs occasionally because of viral or bacterial infection.

Building on this foundation of heart structure, we first explain how action potentials are initiated and spread throughout the heart (Section 8.3), and then discuss how this electrical activity brings about coordinated pumping of the heart (Section 8.4).

Check Your Understanding 8.1

1. Schematically draw the relationship of the pulmonary circulation and the systemic circulation to the chambers of the heart.
2. Name and discuss the functions of the four heart valves.
3. Describe the three layers of the heart walls.

8.3 | Electrical Activity of the Heart

The heart contracts, or beats, rhythmically as a result of action potentials that it generates by itself, a property called **autorhythmicity** (*auto* means “self”). These action potentials sweep across the cardiac muscle cell membranes to cause the contractions necessary to eject blood from the heart. There are two specialized types of cardiac muscle cells:

1. **Contractile cells**, which account for 99 percent of all cardiac muscle cells, do the mechanical work of pumping. These working cells normally do not initiate their own action potentials.
2. In contrast, the small but extremely important remainder of the cardiac cells, the **autorhythmic cells**, do not contract but instead are specialized for initiating and conducting the action potentials responsible for contraction of the working cells.

Cardiac autorhythmic cells

In contrast to the cardiac contractile cells, in which the membrane remains at constant resting potential unless the cell is stimulated, the cardiac autorhythmic cells do not have a defined resting potential. Instead, they display *pacemaker activity*; that is, their membrane potential slowly depolarizes, or drifts, between action potentials until threshold is reached, at which time the membrane fires or generates an action potential. An autorhythmic cell membrane's slow drift to threshold is called the **pacemaker potential** (▶ Figure 8-7). Through repeated cycles of drift and fire, these autorhythmic cells cyclically initiate action potentials, which then spread throughout the heart to trigger rhythmic beating without any nervous stimulation.

▶ **FIGURE 8-7 Pacemaker activity of cardiac autorhythmic cells.** The first half of the pacemaker potential is due to activation of I_f , whereas the second half is due to opening of T-type Ca^{2+} channels. Once threshold is reached, the rising phase of the action potential is due to opening of L-type Ca^{2+} channels, whereas the falling phase is due to opening of K^+ channels.

PACEMAKER POTENTIAL AND ACTION POTENTIAL IN AUTORHYTHMIC CELLS

Complex interactions of several different ionic mechanisms are responsible for the pacemaker potential. The first pacemaker current to be identified was given the name I_f (“f” for current and “f” for funny). This current has very different characteristics from most cardiac ion channels in that this current is activated upon hyperpolarization. Once activated, both potassium and sodium move into the cell. This inward movement of cations causes the slow depolarization that is characteristic of pacemaker cells. I_f channels have been identified as part of the hyperpolarization-activated cyclic nucleotide-gated channel (HCN) family. This is important as it not only indicates that these ion channels are hyperpolarizing but that their activity can also be modulated by cyclic nucleotides, which function as second messengers in most cell types.

Another ion channel thought to contribute to the pacemaker potential is a transient calcium (Ca^{2+}) channel: **T-type Ca^{2+} channel ($I_{\text{Ca,T}}$)**. These ion channels differ from the longer-lasting, voltage-gated Ca^{2+} channel, **L-type Ca^{2+} channel ($I_{\text{Ca,L}}$)**, in that they open at lower membrane potentials. This means that the T-type Ca^{2+} channels begin to open during the slow depolarization before the membrane reaches threshold. The resultant brief influx of Ca^{2+} further depolarizes the membrane, helping to bring it to threshold.

Once threshold is reached, the rising phase of the action potential occurs in response to activation of L-type Ca^{2+} channels and a subsequently large influx of Ca^{2+} . The Ca^{2+} -induced rising phase of a cardiac pacemaker cell differs from that in other excitable cells, where Na^+ influx rather than Ca^{2+} influx swings the potential in the positive direction. Unlike cardiac muscle cells, true pacemaker cells, found in the core of the pacemaker region, do not have voltage-gated Na^+ channels. At threshold, L-type Ca^{2+} channels open, causing Ca^{2+} influx and depolarization of the membrane potential. The rate of this depolarization is slower than that seen in cells with Na^+ channels.

The falling phase is due, as usual, to the potassium (K^+) efflux that occurs when K^+ permeability increases as a result of activation of voltage-gated K^+ channels (I_K). After the action potential is over, slow closure of these K^+ channels coupled with the opening of I_f channels initiates the next slow depolarization to threshold.

The sinoatrial node

The specialized noncontractile cardiac cells capable of autorhythmicity lie in the following specific sites (▶ Figure 8-8):

1. The **sinoatrial node (SA node)**, a small, specialized region in the right atrial wall near the opening of the superior vena cava.
2. The **atrioventricular node (AV node)**, a small bundle of specialized cardiac muscle cells located at the base of the right atrium near the septum, just above the junction of the atria and ventricles.
3. The **bundle of His (atrioventricular bundle)**, a tract of specialized cells that originates at the AV node and enters

► FIGURE 8-8 Specialized conduction system of the heart

the interventricular septum. Here, it divides to form the right and left bundle branches that travel down the septum, curve around the tip of the ventricular chambers, and travel back toward the atria along the outer walls.

4. **Purkinje fibres**, small terminal fibres that extend from the bundle of His and spread throughout the endocardial surface of the ventricular myocardium, much like small twigs of a tree branch.

NORMAL PACEMAKER ACTIVITY

Because these various autorhythmic cells have different rates of slow depolarization to threshold, the rates at which they are normally capable of generating action potentials also differ (Table 8-1). The heart cells with the fastest rate of action potential initiation are localized in the SA node. Once an action potential occurs in any cardiac muscle cell, it is propagated throughout the rest of the myocardium via gap junctions and the specialized conduction system. Therefore, the SA node, which normally has the fastest rate of autorhythmicity, at 70 to

80 action potentials per minute, drives the rest of the heart at this rate and thus is known as the **pacemaker** of the heart. That is, the entire heart becomes excited, triggering the contractile cells to contract and the heart to beat at the pace or rate set by SA node autorhythmicity, normally at 70 to 80 beats per minute. The other autorhythmic tissues cannot assume their own naturally slower rates, because they are activated by action potentials originating in the SA node before they can reach threshold at their own, slower rhythm.

The following analogy shows how the SA node drives the rest of the heart at its own pace. Suppose a train has 100 cars, 3 of which are equipped with engines and are capable of moving on their own; the other 97 cars must be pulled. One of the engine cars (the SA node) can travel at 70 km/h on its own, another engine car (the AV node) at 50 km/h, and the last engine car (the Purkinje fibres) at 30 km/h. If all these cars are joined, the engine car that can travel at 70 km/h will pull the rest of the cars at that speed. The engine cars that can travel at lower speeds on their own will be pulled at a faster speed by the car containing the fastest engine and therefore cannot assume their own slower rate as long as they are being driven by this faster car. The other 97 cars (nonautorhythmic, contractile cells), being unable to move on their own, will likewise travel at whatever speed the fastest car pulls them.

ABNORMAL PACEMAKER ACTIVITY

Clinical Note If for some reason the fastest engine car breaks down (SA node damage), the next-fastest engine car (AV node) takes over, and the entire train travels at 50 km/h; that is, if the SA node becomes nonfunctional, the AV node assumes pacemaker activity. The non-SA-nodal autorhythmic tissues are **latent pacemakers** that can take over, although at a lower rate, if the normal pacemaker fails.

If impulse conduction becomes blocked between the atria and the ventricles, the atria continue to contract at the typical rate of 70 beats per minute, and the ventricular tissue, not being driven by the faster SA nodal rate, assumes its own much slower autorhythmic rate of about 30 beats per minute, initiated by the ventricular autorhythmic cells (Purkinje fibres). This situation is like a breakdown of the second engine car (AV node) so that the lead engine car (SA node) becomes disconnected from the slow third engine-containing car (Purkinje fibres) and the rest of the cars. The lead engine car continues at 70 km/h, while the rest of the train proceeds at 30 km/h. This **complete heart block** occurs when the conducting tissue between the atria and ventricles is damaged, as, for example, during a heart attack, and becomes nonfunctional. A ventricular rate of 30 beats per minute will support only a very sedentary existence; in fact, the patient usually becomes comatose.

When a person has an abnormally low heart rate, as in SA node failure or heart block, an **artificial pacemaker** can be used. Such an implanted device rhythmically generates impulses that spread throughout the heart to drive both the atria and the ventricles at the typical rate of 70 beats per minute.

Occasionally an area of the heart, such as a Purkinje fibre, becomes overly excitable and depolarizes more rapidly than the SA node (the slow engine car suddenly goes faster than the lead

■ TABLE 8-1 Normal Rate of Action Potential Discharge in Autorhythmic Tissues of the Heart

Tissue	Action Potentials per Minute*
SA Node (normal pacemaker)	70–80
AV Node	40–60
Bundle of His and Purkinje Fibres	20–40

*In the presence of sympathetic tone; see p. 189 and p. 367.

engine car). This abnormally excitable area, an **ectopic focus**, initiates a premature action potential that spreads throughout the rest of the heart before the SA node can initiate a normal action potential (*ectopic* means “out of place”). An occasional abnormal impulse from a ventricular ectopic focus produces a **premature ventricular contraction (PVC)**. If the ectopic focus continues to discharge at its more rapid rate, pacemaker activity shifts from the SA node to the ectopic focus. The heart rate abruptly becomes greatly accelerated and continues this rapid rate for a variable time period until the ectopic focus returns to normal. Such overly irritable areas may be associated with organic heart disease, but more frequently they occur in response to anxiety, lack of sleep, or excess caffeine, nicotine, or alcohol consumption.

We now turn our attention to how an action potential, once initiated, is conducted throughout the heart.

Cardiac excitation

Once initiated in the SA node, an action potential spreads throughout the rest of the heart. For efficient cardiac function, the spread of excitation should satisfy three criteria:

1. *Atrial excitation and contraction should be complete before the onset of ventricular contraction.* Complete ventricular filling requires that atrial contraction precede ventricular contraction. During cardiac relaxation, the AV valves are open because pressure is lower in the ventricles compared to the atria, so venous blood entering the atria continues to flow directly into the ventricles. Almost 80 percent of ventricular filling occurs by this means before atrial contraction. When the atria do contract, more blood is squeezed into the ventricles to complete ventricular filling. Ventricular contraction then occurs to eject blood from the heart into the arteries.

If the atria and ventricles were to contract simultaneously, the AV valves would close immediately, because ventricular pressures would greatly exceed atrial pressures. The ventricles have much thicker walls and, accordingly, can generate more pressure. Atrial contraction would be unproductive, because the atria could not squeeze blood into the ventricles through closed valves. Therefore, to ensure complete filling of the ventricles—to obtain the remaining 20 percent of ventricular filling that occurs during atrial contraction—the atria must become excited and contract before ventricular excitation and contraction. During a normal heartbeat, atrial contraction occurs about 160 msec (millisecond) before ventricular contraction.

2. Excitation of cardiac muscle fibres should be coordinated to ensure that each heart chamber contracts as a unit to pump efficiently. If the muscle fibres in a heart chamber became excited and contracted randomly rather than contracting simultaneously in a coordinated fashion, they would be unable to eject blood. A smooth, uniform ventricular contraction is essential to squeeze out the blood. As an analogy, assume you have a basting syringe full of water. If you merely poke a finger here or there into the

rubber bulb of the syringe, you will not eject much water. However, if you compress the bulb in a smooth, coordinated fashion, you can squeeze out the water.

In a similar manner, contraction of isolated cardiac muscle fibres is not successful in pumping blood. Such random, uncoordinated excitation and contraction of the cardiac cells is known as **fibrillation**. Fibrillation of the ventricles is much more serious than atrial fibrillation. Ventricular fibrillation rapidly causes death, because the heart cannot pump blood into the arteries. This condition can often be corrected by **electrical defibrillation**, in which a very strong electrical current is applied on the chest wall. When this current reaches the heart, it stimulates (depolarizes) all parts of the heart simultaneously. Usually the first part of the heart to recover is the SA node, which takes over pacemaker activity, once again initiating impulses that trigger the synchronized contraction of the rest of the heart.

3. The pair of atria and pair of ventricles should be functionally coordinated so that both members of the pair contract simultaneously. This coordination permits synchronized pumping of blood into the pulmonary and systemic circulation.

The normal spread of cardiac excitation is carefully orchestrated to ensure that these criteria are met and the heart functions efficiently (► Figure 8-9; also see Figure 8-8). We now elaborate on these three factors responsible for efficient cardiac function.

ATRIAL EXCITATION

An action potential originating in the SA node first spreads throughout both atria, primarily from cell to cell via gap junctions. In addition, several poorly delineated, specialized

© 2016 Cengage

► **FIGURE 8-9 Spread of cardiac excitation.** An action potential initiated at the SA node first spreads throughout both atria. Its spread is facilitated by two specialized atrial conduction pathways, the interatrial and internodal pathways. The AV node is the only point where an action potential can spread from the atria to the ventricles. From the AV node, the action potential spreads rapidly throughout the ventricles, hastened by a specialized ventricular conduction system consisting of the bundle of His and Purkinje fibres.

conduction pathways speed up conduction of the impulse through the atria.

- The **interatrial pathway** extends from the SA node within the right atrium to the left atrium. Because this pathway rapidly transmits the action potential from the SA node to the pathway's termination in the left atrium, a wave of excitation can spread across the gap junctions throughout the left atrium at the same time excitation is similarly spreading throughout the right atrium. This ensures that both atria become depolarized to contract simultaneously.
- The **internodal pathway** extends from the SA node to the AV node. The AV node is the only point of electrical contact between the atria and ventricles; in other words, because the atria and ventricles are structurally connected by electrically nonconductive fibrous tissue, the only way an action potential in the atria can spread to the ventricles is by passing through the AV node. The internodal conduction pathway directs the spread of an action potential originating at the SA node to the AV node to ensure sequential contraction of the ventricles following atrial contraction. Hastened by this pathway, the action potential arrives at the AV node within 30 msec of SA node firing.

CONDUCTION BETWEEN THE ATRIA AND THE VENTRICLES

The action potential is conducted relatively slowly through the AV node. This slowness is advantageous because it allows time for complete ventricular filling. The impulse is delayed about 100 msec (the **AV nodal delay**), which enables the atria to become completely depolarized and to contract, emptying their contents into the ventricles, before ventricular depolarization and contraction occur.

VENTRICULAR EXCITATION

After the AV nodal delay, the impulse travels rapidly down the septum via the right and left branches of the bundle of His and throughout the ventricular myocardium via the Purkinje fibres. The network of fibres in this ventricular conduction system is specialized for rapid propagation of action potentials. Its presence hastens and coordinates the spread of ventricular excitation to ensure that the ventricles contract as a unit. The action potential is transmitted through the entire Purkinje fibre system within 30 msec.

Although this system carries the action potential rapidly to a large number of cardiac muscle cells, it does not terminate on every cell. The majority of Purkinje fibres terminate on ventricular muscle cells near the endocardial surface. The impulse quickly spreads across the ventricular wall to the epicardial surface by means of gap junctions.

The ventricular conduction system is more highly organized and more important than the interatrial and internodal conduction pathways. Because the ventricular mass is so much larger than the atrial mass, a rapid conduction system is crucial to hasten the spread of excitation in the ventricles. Purkinje fibres can transmit an action potential six times faster than the ventricular syncytium of contractile cells can. If the

entire ventricular depolarization process depended on cell-to-cell spread of the impulse via gap junctions, the ventricular tissue immediately next to the AV node would become excited and contract before the impulse had even passed to the heart apex. This, of course, would not allow efficient pumping. Rapid conduction of the action potential down the bundle of His and its swift, diffuse distribution throughout the Purkinje network lead to almost simultaneous activation of the ventricular myocardial cells in both ventricular chambers, which ensures a single, smooth, coordinated contraction that can efficiently eject blood into both the systemic and pulmonary circulations at the same time.

Cardiac contractile cells

The action potential in cardiac contractile cells, although initiated by the nodal pacemaker cells, varies considerably in its ionic mechanisms and shape from the action potentials generated at the SA node (compare Figure 8-7 and ▶ Figure 8-10). Unlike the membrane of autorhythmic cells, the membrane of contractile cells remains essentially at rest at about -80 millivolts until excited by electrical activity propagated from the pacemaker. Once the membrane of a ventricular myocardial contractile cell is excited, an action potential is generated by a complicated interplay of permeability changes and membrane potential changes, as follows (Figure 8-10):

1. During the rising phase of the action potential, the membrane potential rapidly reverses to a positive value approaching $+50$ mV, due to the activation of voltage-gated Na^+ channels and the subsequent rapid entry of Na^+ into the cell, as it does in other excitable cells undergoing an action potential (p. 63).
2. The rapid depolarization brought about by activation of the "fast" Na^+ channels causes other voltage-dependent ion channels to be activated. The first is a transient outward

▶ **FIGURE 8-10** Action potential in contractile cardiac muscle cells. The action potential in cardiac contractile cells differs considerably from the action potential in cardiac autorhythmic cells (compare with Figure 8-7).

K^+ channel (I_{to}) that rapidly moves K^+ out of the cell to counter the influx of Na^+ . The second is the “slow” L-type Ca^{2+} channel ($I_{Ca,L}$), and the third is yet another type of voltage-gated K^+ channel, the delayed rectifier (I_K). The temporary balance of these inward and outward currents results in the characteristic plateau phase of the cardiac action potential, which can last for several hundred milliseconds.

3. Eventually, there is a time-dependent inactivation of both the transient outward K^+ and inward L-type Ca^{2+} channels that disrupts the ionic flux balance of the plateau phase. At this time, the outward delayed rectifier K^+ current dominates and, as in other excitable cells, the cell returns to resting potential as K^+ leaves the cell.
4. The resting membrane potential is maintained by a K^+ channel called the inward rectifier K^+ channel, which is unique in that it can move K^+ both in and out of the cell to keep the resting membrane constant.

Let's now see how this action potential brings about contraction.

Calcium release from the sarcoplasmic reticulum

In cardiac contractile cells, the L-type Ca^{2+} channels lie primarily in the T tubules. As you learned from the preceding discussion, these voltage-gated channels open during a local action potential. Upon depolarization of the cell membrane, these L-type Ca^{2+} channels open allowing the influx of Ca^{2+} . Once inside the cell, this Ca^{2+} can directly interact with the contractile machinery or it can cause the further Ca^{2+} release from internal stores. Located within the membrane of the sarcoplasmic reticulum is a protein called the *ryanodine receptor*. The ryanodine receptor is a Ca^{2+} release channel that, when activated by Ca^{2+} entering the cell through L-type Ca^{2+} channels, causes the sarcoplasmic reticulum to release its Ca^{2+} stores. This process of Ca^{2+} from the ECF interacting with ryanodine receptors to further increase cytosolic Ca^{2+} levels is called **Ca^{2+} -induced Ca^{2+} release**. Depending upon the species, up to 90 percent of the Ca^{2+} needed for cardiac muscle contraction comes from the sarcoplasmic reticulum.

ROLE OF CYTOSOLIC Ca^{2+} IN EXCITATION-CONTRACTION COUPLING

The role of Ca^{2+} within the cytosol is to bind with the troponin-tropomyosin complex and physically pull it aside to allow cross-bridge cycling and contraction (► Figure 8-11). However, unlike skeletal muscle, in which sufficient Ca^{2+} is always released to turn on all the cross bridges, in cardiac muscle the extent of cross-bridge activity varies with the amount of cytosolic Ca^{2+} . As we will show, various regulatory factors can alter the amount of cytosolic Ca^{2+} .

Removal of Ca^{2+} from the cytosol by energy-dependent mechanisms in both the plasma membrane and the sarcoplasmic reticulum restores the blocking action of troponin and tropomyosin, so contraction ceases and the heart muscle relaxes.

► FIGURE 8-11 Excitation-contraction coupling in cardiac contractile cells

INFLUENCE OF ALTERED ECF K^+ AND Ca^{2+} CONCENTRATIONS

Not surprisingly, changes in the ECF concentration of potassium and calcium can have profound effects on the heart. Abnormal levels of K^+ are most important clinically, followed to a lesser extent by Ca^{2+} imbalances. Changes in K^+ concentration in the ECF alter the K^+ concentration gradient between the ICF and ECF. Normally, there is substantially more K^+ inside the cells than in the ECF, but with elevated ECF K^+ levels, this gradient is reduced. Associated with this change is a reduction in resting potential (i.e., the membrane is less negative on the inside than normal because less K^+ leaves). Among the consequences is a tendency to develop ectopic foci as well as cardiac arrhythmias.

An elevated ECF Ca^{2+} concentration, in contrast, augments the strength of cardiac contraction by prolonging the plateau phase of the action potential and by increasing the cytosolic concentration of Ca^{2+} . Contractions tend to be of longer duration, with little time to rest between contractions. Some drugs alter cardiac function by influencing Ca^{2+} movement across the myocardial cell membranes. For example, Ca^{2+} channel-blocking agents, such as *verapamil*, block Ca^{2+} influx during an action potential, thereby reducing the force of cardiac contraction. Other drugs, such as *digitalis*, increase cardiac contractility by inducing an accumulation of cytosolic Ca^{2+} .

Long refractory period

Like other excitable tissues, cardiac muscle has a refractory period. During the absolute refractory period, a second action potential cannot be triggered until an excitable membrane has recovered from the preceding action potential. In skeletal muscle, the refractory period is very short compared with the duration of the resulting contraction, so the fibre can be restimulated before the first contraction is complete to produce summation of contractions. Rapidly repetitive stimulation that does not let the muscle fibre relax between stimulations results in a sustained, maximal contraction known as *tetanus* (see Figure 7-15).

In contrast, cardiac muscle has a long refractory period that lasts about 250 msec because of the prolonged plateau phase of the action potential. This is almost as long as the period of contraction initiated by the action potential; a cardiac muscle fibre contraction averages about 300 msec (► Figure 8-12). Consequently, cardiac muscle cannot be restimulated until contraction

is almost over, which precludes summation of contractions and tetanus of cardiac muscle. This is a valuable protective mechanism, because the pumping of blood requires alternate periods of contraction (emptying) and relaxation (filling). A prolonged tetanic contraction would prove fatal. The heart chambers could not be filled and emptied again.

The chief factor responsible for the long refractory period is inactivation of the Na^+ channels that were activated during the initial Na^+ influx of the rising phase. During the plateau phase of the action potentials, Na^+ channels are inactivated and cannot recover from inactivation until the membrane potential has returned to near resting levels. Only then can the Na^+ channels be activated once again to begin another action potential. It is important to note, however, that even though Na^+ channels are the primary determinant for the long refractory period, factors underlying the maintenance of the plateau phase are also critical because they directly affect the time it takes for Na^+ channels to return to their resting state.

The ECG

The electrical currents generated by cardiac muscle during depolarization and repolarization spread into the tissues around the heart and are conducted through the body fluids. A small part of this electrical activity reaches the body surface, where it can be detected using recording electrodes. The record produced is an **electrocardiogram (ECG)**. (Alternatively, the abbreviation EKG is often used, from the ancient Greek word *kardia* instead of the Latin *cardia* for “heart.”)

Remember three important points when considering what an ECG represents:

1. An ECG is a recording of that part of the electrical activity induced in body fluids by the cardiac impulse that reaches the body surface, not a direct recording of the actual electrical activity of the heart.
2. The ECG is a complex recording representing the *overall* spread of activity throughout the heart during depolarization and repolarization. It is not a recording of a *single* action potential in a single cell at a single point in time. The record at any given time represents the sum of electrical activity in all the cardiac muscle cells, some of which may be generating action potentials while others may not yet be activated. For example, immediately after the SA node fires, the atrial cells are generating action potentials while the ventricular cells are still at resting potential. At a later point, the electrical activity will have spread to the ventricular cells while the atrial cells will be repolarizing. Therefore, the overall pattern of cardiac electrical activity varies with time as the impulse passes throughout the heart.
3. The recording represents comparisons in voltage detected by electrodes at two different points on the body surface, not the actual potential. For example, the ECG does not record a potential at all when the ventricular muscle is either completely depolarized or completely repolarized; both electrodes are viewing the same potential, so no *difference* in potential between the two electrodes is recorded.

► **FIGURE 8-12** Relationship of an action potential and the refractory period to the duration of the contractile response in cardiac muscle

The exact pattern of electrical activity recorded from the body surface depends on the orientation of the recording electrodes. Electrodes may be loosely thought of as the eyes that see the electrical activity, which then is translated into a visible recording, the ECG record. Whether an upward deflection or downward deflection is recorded is determined by the way the electrodes are oriented with respect to the current flow in the heart. For example, the spread of excitation across the heart is seen differently from the right arm, from the left leg, or from a recording directly over the heart. Even though the same electrical events are occurring in the heart, different waveforms representing the same electrical activity result when this activity is recorded by electrodes at different points on the body.

To provide standard comparisons, ECG records routinely consist of 12 conventional electrode systems, or leads. When an electrocardiograph machine is connected to pairs of recording electrodes attached to the body, the specific arrangement of each pair of connections is called a **lead**. The 12 different leads each

record electrical activity in the heart from different locations—six different electrical arrangements from the limbs and six chest leads at various sites around the heart. To provide a common basis for comparison and for recognizing deviations from normal, the same 12 leads are routinely used in all ECG recordings (► Figure 8-13).

The ECG record

Interpretation of the wave configurations recorded from each lead depends on a thorough knowledge about the sequence of cardiac excitation spread and about the position of the heart relative to electrode placement. A normal ECG has three distinct waveforms: the P wave, the QRS complex, and the T wave (► Figure 8-14).

- The **P wave** represents atrial depolarization.
- The **QRS complex** represents ventricular depolarization.
- The **T wave** represents ventricular repolarization.

© 2016 Cengage

► **FIGURE 8-13 Electrocardiogram leads.** (a) The six limb leads include leads I, II, III, aVR, aVL, and aVF. Leads I, II, and III are bipolar leads because two recording electrodes are used. The tracing records the *difference* in potential between the two electrodes. For example, lead I records the difference in potential detected at the right arm and left arm. The electrode placed on the right leg serves as a ground and is not a recording electrode. The aVR, aVL, and aVF leads are unipolar leads. Even though two electrodes are used, only the actual potential under one electrode, the exploring electrode, is recorded. The other electrode is set at zero potential in comparison to the rest of the body. (b) The six chest leads, V1 through V6, are also unipolar leads. The exploring electrode mainly records the electrical potential of the cardiac musculature immediately beneath the electrode in six different locations surrounding the heart.

► FIGURE 8-14 Electrocardiogram waveforms in lead II

Because these shifting waves of depolarization and repolarization bring about the alternating contraction and relaxation of the heart, respectively, the cyclic mechanical events of the heart lag slightly behind the rhythmic changes in electrical activity. The following points about the ECG record should also be noted:

1. Firing of the SA node does not generate enough electrical activity to reach the body surface, so no wave is recorded for SA nodal depolarization. Therefore, the first recorded wave, the P wave, occurs when the impulse or wave of depolarization spreads across the atria.
2. In a normal ECG, no separate wave for atrial repolarization is visible. The electrical activity associated with atrial repolarization normally occurs simultaneously with ventricular depolarization and is masked by the QRS complex.
3. The P wave is much smaller than the QRS complex, because the atria have a much smaller muscle mass than the ventricles and consequently generate less electrical activity.
4. At the following three points in time, no net current flow is taking place in the heart musculature, so the ECG remains at baseline:
 - a. *During the AV nodal delay.* This delay is represented by the interval of time between the end of P and the onset QRS; this segment of the ECG is known as the PR segment. (It is called the **PR segment** rather than the PQ segment because the Q deflection is small and sometimes absent, whereas the R deflection is the dominant wave of the complex.) Current is flowing through the AV node, but the magnitude is too small for the ECG electrodes to detect.
 - b. *When the ventricles are completely depolarized and the cardiac contractile cells are undergoing the plateau phase of their action potential before they repolarize.* This is represented by the **ST segment**. This segment lies between QRS and T; it coincides with the time during

which ventricular activation is complete and the ventricles are contracting and emptying. Note that the ST segment is not a record of cardiac contractile activity. The ECG is a measure of the electrical activity that triggers the subsequent mechanical activity.

- c. *When the heart muscle is completely repolarized and at rest and ventricular filling is taking place, after the T wave and before the next P wave.* This period is called the **TP interval**.

Clinical Connections

Debbie was given an ECG because her symptoms suggested she may be experiencing a heart attack, and the ECG is a very sensitive method to see if something is wrong with the heart. As already discussed, the ST segment represents the period during ventricular depolarization and repolarization. During this time there is no net change in electrical activity of the ventricle, so the ST segment is isoelectric (a flat line at 0 mV). An elevated ST segment is sometimes seen following a myocardial infarction, but interestingly enough, the elevation is not reflective of something happening during the ST segment but rather how the tracing is generated by the ECG machine. The infarcted zone repolarizes slower than the rest of the ventricle, and this causes the illusion of a delayed current moving away from the recording electrode. This current gets interpreted as the baseline (the baseline is normally isoelectric), and since it is more negative than the ST segment, the ST segment appears to be elevated even though the ST segment is still the isoelectric line. Basically, because the ECG machine makes an error in where the isoelectric point is, the true isoelectric point appears elevated.

The ECG diagnosis

Because electrical activity triggers mechanical activity, abnormal electrical patterns are usually accompanied by abnormal contractile activity of the heart. So evaluation of ECG patterns can provide useful information about the status of the heart. The main deviations from normal that can be found through electrocardiography are (1) abnormalities in rate, (2) abnormalities in rhythm, and (3) cardiac myopathies (► Figure 8-15).

ABNORMALITIES IN RATE

The heart rate can be determined from the distance between two consecutive QRS complexes on the calibrated paper used to record an ECG. A rapid heart rate of more than 100 beats per minute is called **tachycardia** (*tachy* means “fast”), whereas a slow heart rate of fewer than 60 beats per minute is called **bradycardia** (*brady* means “slow”).

ABNORMALITIES IN RHYTHM

Rhythm refers to the regularity or spacing of the ECG waves. Any variation from the normal rhythm and sequence of excitation of the heart is termed an **arrhythmia**. It may result from ectopic foci, alterations in SA node pacemaker activity, or interference with conduction. Heart rate is also often altered. *Extrasystoles*, or *premature ventricular contractions*, originating from an ectopic focus are common deviations from normal rhythm. Other

► **FIGURE 8-15** Representative heart conditions detectable through electrocardiography

abnormalities in rhythm easily detected on an ECG include atrial flutter, atrial fibrillation, ventricular fibrillation, and heart block.

Atrial flutter is characterized by a rapid but regular sequence of atrial depolarizations at rates between 200 and 380 beats per minute. The ventricles rarely keep pace with the racing atria. Because the conducting tissue's refractory period is longer than that of the atrial muscle, the AV node is unable to respond to every impulse that converges on it from the atria. Maybe only one out of every two or three atrial impulses successfully passes through the AV node to the ventricles. Such a situation is referred to as a *2:1* or *3:1 rhythm*. The fact that not every atrial impulse reaches the ventricle in atrial flutter is important, because it precludes a rapid ventricular rate of more than 200 beats per minute. Such a high rate would not allow adequate time for ventricular

filling between beats. In such a case, the output of the heart would be reduced to the extent that loss of consciousness or even death could result because of decreased blood flow to the brain.

Atrial fibrillation is characterized by rapid, irregular, uncoordinated depolarizations of the atria with no definite P waves. Accordingly, atrial contractions are chaotic and asynchronized. Because impulses reach the AV node erratically, the ventricular rhythm is also very irregular. The QRS complexes are normal in shape but occur sporadically. Variable lengths of time between ventricular beats are available for ventricular filling. Some ventricular beats come so close together that little filling can occur between beats. When less filling occurs, the subsequent contraction is weaker. In fact, some of the ventricular contractions may be too weak to eject enough blood to produce a palpable wrist pulse. In this situation, if the heart rate is determined directly, either by the apex beat or via the ECG, and the pulse rate is taken concurrently at the wrist, the heart rate will exceed the pulse rate. Such a difference in heart rate and pulse rate is known as a **pulse deficit**. Normally, the heart rate coincides with the pulse rate, because each cardiac contraction initiates a pulse wave as it ejects blood into the arteries.

Ventricular fibrillation is a very serious rhythmic abnormality in which the ventricular musculature exhibits uncoordinated, chaotic contractions. Multiple impulses travel erratically in all directions around the ventricles. The ECG tracing in ventricular fibrillations is very irregular, with no detectable pattern or rhythm. When contractions are so disorganized, the ventricles are ineffectual as pumps. If circulation is not restored in less than four minutes through external cardiac compression or electrical defibrillation, irreversible brain damage occurs, and death is imminent.

Another type of arrhythmia, **heart block**, arises from defects in the cardiac conducting system. The atria still beat regularly, but the ventricles occasionally fail to be stimulated and thus do not contract following atrial contraction. Impulses between the atria and ventricles can be blocked to varying degrees. In some forms of heart block, only every second or third atrial impulse is passed to the ventricles. This is known as *2:1* or *3:1 block*, which can be distinguished from the *2:1* or *3:1* rhythm associated with atrial flutter by the rates involved. In heart block, the atrial rate is normal, but the ventricular rate is considerably below normal; in atrial flutter the atrial rate is very high, and the ventricular rate is normal or above-normal. **Complete heart block** is characterized by complete dissociation between atrial and ventricular activity, which means impulses from the atria are not conducted to the ventricles at all. The SA node continues to govern atrial depolarization, but the ventricles generate their own impulses at a rate much slower than that of the atria. On the ECG, the P waves exhibit a normal rhythm. The QRS and T waves also occur regularly, but they are much slower than the P waves and completely independent of P wave rhythm. Because atrial and ventricular activity is not synchronized, waves for atrial repolarization may appear, since they are no longer masked by the QRS complex.

CARDIAC MYOPATHIES

Abnormal ECG waves are also important for recognizing and assessing **cardiac myopathies** (damage of the heart muscle). **Myocardial ischemia** is inadequate delivery of oxygenated blood to the heart tissue. Actual death, or **necrosis**, of heart muscle

cells occurs when a blood vessel supplying that area of the heart becomes blocked or ruptured. This condition is **acute myocardial infarction**, commonly called a **heart attack**. Abnormal QRS waveforms appear when part of the heart muscle becomes necrotic. In addition to ECG changes, because damaged heart muscle cells release characteristic enzymes into the blood, the level of these enzymes in the blood provides a further index of the extent of myocardial damage.

Interpretation of an ECG is a complex task requiring extensive knowledge and training. The foregoing discussion is not by any means intended to make you an ECG expert, but seeks to give you an appreciation of the ways in which the ECG can be used as a diagnostic tool, as well as to present an overview of some of the more common abnormalities of heart function.

Check Your Understanding 8.2

1. Draw two graphs comparing the electrical activity in a cardiac autorhythmic cell and in a cardiac contractile cell. Label the ion movement responsible for each change in potential.
2. List the autorhythmic tissues of the heart, and indicate the normal rate of action potential discharge of each.
3. Explain why no separate wave for atrial repolarization is visible on a normal ECG.

8.4 Mechanical Events of the Cardiac Cycle

The mechanical events of the cardiac cycle—contraction, relaxation, and the resultant changes in blood flow through the heart—are brought about by the rhythmic changes in cardiac electrical activity.

Contracting and relaxing

The cardiac cycle consists of alternate periods of **systole** (contraction and emptying) and **diastole** (relaxation and filling). Contraction results from the spread of excitation across the heart, whereas relaxation follows the subsequent repolarization of the cardiac musculature. The atria and ventricles go through separate cycles of systole and diastole. Unless otherwise stated, the terms *systole* and *diastole* refer to what's happening with the ventricles.

The following discussion and corresponding ▶ Figure 8-16 correlate various events that occur concurrently during the cardiac cycle, including ECG features, pressure changes, volume changes, valve activity, and heart sounds. Only the events on the left side of the heart are described, but keep in mind that identical events are occurring on the right side of the heart, except that the pressures are lower. To complete one full cardiac cycle, our discussion begins and ends with ventricular diastole.

MID-VENTRICULAR DIASTOLE

During most of ventricular diastole, the atrium is still also in diastole. This stage corresponds to the TP interval on the ECG—the interval after ventricular repolarization and before another

atrial depolarization. Because of the continuous inflow of blood from the venous system into the atrium, atrial pressure slightly exceeds ventricular pressure even though both chambers are relaxed. As a result of this pressure differential, the AV valve is open, and blood flows directly from the atrium into the ventricle throughout ventricular diastole (**A** in Figure 8-16). As a result of this passive filling, the ventricular volume slowly continues to rise even before atrial contraction takes place.

LATE VENTRICULAR DIASTOLE

Late in ventricular diastole, the SA node reaches threshold and fires. The impulse spreads throughout the atria, which appears on the ECG as the P wave. Atrial depolarization brings about atrial contraction, raising the atrial pressure and squeezing more blood into the ventricle. The excitation–contraction coupling process takes place during the short delay between the P wave and the rise in atrial pressure. The corresponding rise in ventricular pressure that occurs simultaneously with the rise in atrial pressure is due to the additional volume of blood added to the ventricle by atrial contraction (**B** in Figure 8-16). Throughout atrial contraction, atrial pressure still slightly exceeds ventricular pressure, so the AV valve remains open.

END OF VENTRICULAR DIASTOLE

Ventricular diastole ends at the onset of ventricular contraction. By this time, atrial contraction and ventricular filling have completed. The volume of blood in the ventricle at the end of diastole is known as the **end-diastolic volume (EDV)**, which averages about 135 mL. No more blood is added to the ventricle during this cycle. Therefore, the end-diastolic volume is the maximum amount of blood that the ventricle will contain during this cycle.

VENTRICULAR EXCITATION AND ONSET OF VENTRICULAR SYSTOLE

After atrial excitation, the impulse travels through the AV node and specialized conduction system to excite the ventricle. Simultaneously, the atria are contracting. By the time ventricular activation is complete, atrial contraction is already over. The QRS complex represents this ventricular excitation, which induces ventricular contraction. The ventricular pressure sharply increases shortly after the QRS complex, signalling the onset of ventricular systole. The slight delay between the QRS complex and the actual onset of ventricular systole is the time required for the excitation–contraction coupling process to occur. As ventricular contraction begins, ventricular pressure immediately exceeds atrial pressure. This backward-pressure differential forces the AV valve to close.

ISOVOLUMETRIC VENTRICULAR CONTRACTION

After ventricular pressure exceeds atrial pressure and the AV valve has closed, to open the aortic valve, the ventricular pressure must continue to increase until it exceeds aortic pressure. Therefore, after closing of the AV valve and before opening of the aortic valve, there is a brief period of time when the ventricle remains a closed chamber (**C** in Figure 8-16). Because all valves are closed, no blood can enter or leave the ventricle during this time. This interval is termed as the period of

FIGURE 8-16 Cardiac cycle. This graph depicts various events that occur concurrently during the cardiac cycle. Follow each horizontal strip across to see the changes that take place in the electrocardiogram; aortic, ventricular, and atrial pressures; ventricular volume; and heart sounds throughout the cycle. The last half of diastole, one full systole and diastole (one full cardiac cycle), and another systole are shown for the left side of the heart. Follow each vertical strip downward to see what happens simultaneously with each of these factors during each phase of the cardiac cycle. See pp. 361–364 for a detailed explanation of the circled letters. The sketches of the heart illustrate the flow of O_2 -poor (dark blue) and O_2 -rich (bright red) blood in and out of the ventricles during the cardiac cycle.

isovolumetric ventricular contraction (*isovolumetric* means “constant volume and length”). Because no blood enters or leaves the ventricle, the ventricular chamber stays at constant volume, and the muscle fibres stay at constant length. This isovolumetric condition is similar to an isometric contraction in skeletal muscle. During isovolumetric ventricular contraction, ventricular pressure continues to increase as the volume remains constant.

VENTRICULAR EJECTION

When ventricular pressure exceeds aortic pressure, the aortic valve is forced open and ejection of blood begins (**D** in Figure 8-16). The amount of blood pumped out of each ventricle with each contraction is called the **stroke volume (SV)**. At rest, stroke volume is approximately 70 mL. The aortic pressure curve rises as blood becomes forced into the aorta from the ventricle faster than it can drain off into the smaller vessels at the other end. The ventricular volume decreases substantially as blood is rapidly pumped out. Ventricular systole includes both the period of isovolumetric contraction and the ventricular ejection phase.

END OF VENTRICULAR SYSTOLE

The ventricle does not empty completely during ejection. Normally, only about half the blood within the ventricle at the end of diastole is pumped out during the subsequent systole. The amount of blood left in the ventricle at the end of systole when ejection is complete is the **end-systolic volume (ESV)**, which averages about 65 mL. This is the least amount of blood that the ventricle will contain during this cycle.

The difference between the volume of blood in the ventricle before contraction and the volume after contraction is the amount of blood ejected during the contraction; that is, $EDV - ESV = SV$. In our example, the end-diastolic volume is 135 mL, the end-systolic volume is 65 mL, and the stroke volume is 70 mL.

VENTRICULAR REPOLARIZATION AND ONSET OF VENTRICULAR DIASTOLE

The T wave signifies ventricular repolarization at the end of ventricular systole. As the ventricle starts to relax, on repolarization, ventricular pressure falls below aortic pressure and the aortic valve closes. Closure of the aortic valve produces a disturbance, or notch, on the aortic pressure curve—the **dirotic notch**. No more blood leaves the ventricle during this cycle, because the aortic valve has closed.

ISOVOLUMETRIC VENTRICULAR RELAXATION

When the aortic valve closes, the AV valve has not yet opened, because ventricular pressure still exceeds atrial pressure, so no blood can enter the ventricle from the atrium. Therefore, all valves are once

again closed for a brief period of time known as **isovolumetric ventricular relaxation** (**E** in Figure 8-16). The muscle fibre length and chamber volume remain constant. No blood leaves or enters as the ventricle continues to relax and the pressure steadily falls.

VENTRICULAR FILLING

When ventricular pressure falls below atrial pressure, the AV valve opens, and ventricular filling occurs again. Ventricular diastole includes both the period of isovolumetric ventricular relaxation and the ventricular filling phase.

Atrial repolarization and ventricular depolarization occur simultaneously, so the atria are in diastole throughout ventricular systole. Blood continues to flow from the pulmonary veins into the left atrium. As this incoming blood pools in the atrium, atrial pressure rises continuously. When the AV valve opens at the end of ventricular systole, blood that accumulated in the atrium during ventricular systole pours rapidly into the ventricle (**A** again). Ventricular filling thus occurs rapidly at first because of the increased atrial pressure resulting from the accumulation of blood in the atria. Then ventricular filling slows down because the accumulated blood has already been delivered to the ventricle, and atrial pressure starts to fall. During this period of reduced filling, blood continues to flow from the pulmonary veins into the left atrium and through the open AV valve into the left ventricle. During late ventricular diastole, when the ventricle is filling slowly, the SA node fires again, and the cardiac cycle starts over.

When the body is at rest, one complete cardiac cycle lasts 800 msec, with 300 msec devoted to ventricular systole and 500 msec taken up by ventricular diastole. Significantly, much of ventricular filling occurs early in diastole during the rapid-filling phase (**▶** Figure 8-17). During times of rapid heart rate, diastole length is shortened much more than systole length is. For example, if the heart rate increases from 75 to 180 beats per minute, the duration of diastole decreases about 75 percent, from 500 msec to 125 msec. This greatly reduces the time available for

▶ FIGURE 8-17 Ventricular filling profiles during normal and rapid heart rates. Because much of ventricular filling occurs early in diastole during the rapid-filling phase, filling is not seriously impaired when diastolic time is reduced as a result of an increase in heart rate.

ventricular relaxation and filling. However, because much ventricular filling is accomplished during early diastole, filling is not necessarily impaired during periods of increased heart rate, such as during exercise. Also contributing to this is the volume of ventricular filling that is attributed to atrial contraction, the relative contribution of which increases with higher heart rates. There is a limit, however, to how rapidly the heart can beat without decreasing the period of diastole to the point that ventricular filling is severely impaired. At heart rates greater than 200 beats per minute, diastolic time is too short to allow adequate ventricular filling. With inadequate filling, the resultant cardiac output is deficient. Normally, ventricular rates do not exceed 200 beats per minute, because the relatively long refractory period of the AV node does not allow impulses to be conducted to the ventricles more frequently than this.

Heart sounds

Two major heart sounds normally can be heard with a stethoscope during the cardiac cycle. The **first heart sound** is low-pitched, soft, and relatively long—often said to sound like “lub.” The **second heart sound** has a higher pitch and is shorter and sharper—often said to sound like “dup.” Thus, one normally hears “lub-dup-lub-dup-lub-dup...” The first heart sound is associated with closure of the AV valves, whereas the second sound is associated with closure of the semilunar valves (see the blue line associated with Heart sounds in Figure 8-16). Opening of valves does not produce any sound.

The sounds are caused by vibrations set up within the walls of the ventricles and major arteries during valve closure, not by the valves snapping shut. Because the AV valves close at the onset of ventricular contraction, when ventricular pressure first exceeds atrial pressure, the first heart sound signals the onset of ventricular systole. The semilunar valves close at the onset of ventricular relaxation, when the left and right ventricular pressures fall below the aortic and pulmonary artery pressures, respectively. The second heart sound, therefore, signals the onset of ventricular diastole.

HEART MURMURS

Abnormal heart sounds, or **murmurs**, are usually (but not always) associated with cardiac disease. Murmurs not involving heart pathology, so-called **functional murmurs**, are more common in young people.

Blood normally flows in a *laminar* fashion; that is, layers of the fluid slide smoothly over each other (*lamina* means “layer”). Laminar flow does not produce any sound. When blood flow becomes turbulent, however, a sound can be heard. Such an abnormal sound is due to vibrations that the turbulent flow creates in the surrounding structures.

STENOTIC AND INSUFFICIENT VALVES

The most common cause of turbulence is valve malfunction, either a stenotic or an insufficient valve. A **stenotic valve** is a stiff, narrowed valve that does not open completely. Blood

must be forced through the constricted opening at tremendous velocity, resulting in turbulence that produces an abnormal whistling sound similar to the sound produced when you force air rapidly through narrowed lips to whistle.

An **insufficient or incompetent valve** is one that cannot close completely, usually because the valve edges are scarred and do not fit together properly. Turbulence is produced when blood flows backward through the insufficient valve and collides with blood moving in the opposite direction, creating a swishing or gurgling murmur. Such backflow of blood is known as **regurgitation**. An insufficient heart valve is often called a **leaky valve**, because it lets blood leak back through at a time when the valve should be closed.

Most often, both valvular stenosis and insufficiency are caused by **rheumatic fever**, an autoimmune (immunity against self) disease triggered by a *streptococcus* bacterial infection. Antibodies formed against toxins produced by these bacteria interact with many of the body’s own tissues, resulting in immunological damage. The heart valves are among the most susceptible tissues in this regard. Large, haemorrhagic, fibrous lesions form along the inflamed edges of an affected heart valve, causing the valve to become thickened, stiff, and scarred. Sometimes the leaflet edges permanently adhere to each other. Depending on the extent and specific nature of the lesions, the valve may become either stenotic or insufficient or some degree of both.

TIMING OF MURMURS

The valve involved and the type of defect can usually be detected by the *location* and *timing* of the murmur. Each heart valve can be heard best at a specific location on the chest. Noting where a murmur is loudest helps the diagnostician tell which valve is involved.

The timing of the murmur refers to the part of the cardiac cycle during which the murmur is heard. Recall that the first heart sound signals the onset of ventricular systole, and the second heart sound signals the onset of ventricular diastole. Therefore, a murmur between the first and second heart sounds (lub-murmur-dup, lub-murmur-dup) is a **systolic murmur**. A **diastolic murmur**, in contrast, occurs between the second and first heart sound (lub-dup-murmur, lub-dup-murmur). The sound of the murmur characterizes it as either a stenotic (whistling) murmur or an insufficient (swishy) murmur. Armed with these facts, a trained person can determine the cause of a valvular murmur (■ Table 8-2). As an example, a whistling murmur (denoting a stenotic valve) that occurs between the first and second heart sounds (denoting a systolic murmur) indicates stenosis in a valve that should be open during systole. The stenotic valve could be either the aortic or the pulmonary semilunar valve through which blood is being ejected. Identifying which of these valves is stenotic is accomplished by finding where the murmur is best heard.

The main concern with heart murmurs, of course, is not the murmur itself but the harmful circulatory results of the defect.

■ **TABLE 8-2** Timing and Type of Murmur Associated with Various Heart Valve Disorders

Pattern Heard on Auscultation	Type of Valve Defect	Timing of Murmur	Valve Disorder	Comment
Lub-Whistle-Dup	Stenotic	Systolic	Stenotic semilunar valve	A whistling systolic murmur signifies that a valve that should be open during systole (a semilunar valve) does not open completely.
Lub-Dup-Whistle	Stenotic	Diastolic	Stenotic AV valve	A whistling diastolic murmur signifies that a valve that should be open during diastole (an AV valve) does not open completely.
Lub-Swish-Dup	Insufficient	Systolic	Insufficient AV valve	A swishy systolic murmur signifies that a valve that should be closed during systole (an AV valve) does not close completely.
Lub-Dup-Swish	Insufficient	Diastolic	Insufficient semilunar valve	A swishy diastolic murmur signifies that a valve that should be closed during diastole (a semi-lunar valve) does not close completely.

Check Your Understanding 8.3

1. Define *systole* and *diastole*.
2. State the pressure relationships among the aortic, atrial, and ventricular pressures (e.g., ventricular pressure > aortic pressure > atrial pressure) during each of these phases of the cardiac cycle: (1) ventricular filling, (2) isovolumetric ventricular contraction, (3) ventricular ejection, and (4) isovolumetric ventricular relaxation (think what pressure relationships must exist for the valves to be open or closed as appropriate in each phase).
3. How do heart sounds relate to the cardiac cycle?

8.5 | Cardiac Output and its Control

Cardiac output (CO) is the volume of blood pumped by *each ventricle* per minute (not the total amount of blood pumped by the heart). During any period of time, the volume of blood flowing through the pulmonary circulation is the same as the volume flowing through the systemic circulation. Therefore, the cardiac output from each ventricle normally is the same, although on a beat-to-beat basis, minor variations may occur (Appendix F lists reference values).

Cardiac output

The two determinants of cardiac output are *heart rate* (beats per minute) and *stroke volume* (volume of blood pumped per beat or stroke). The average resting heart rate is 70 beats per minute,

established by SA node rhythmicity; and the average resting stroke volume is 70 mL per beat, producing an average cardiac output of 4900 mL/min, or close to 5 L/min:

$$\begin{aligned}
 \text{Cardiac output (CO)} &= \text{heart rate} \times \text{stroke volume} \\
 &= 70 \text{ beats/min} \times 70 \text{ mL/beat} \\
 &= 4900 \text{ mL/min} \approx 5 \text{ L/min}
 \end{aligned}$$

Because the body's total blood volume averages 5–5.5 L (which may expand to 6 litres in some athletes), each half of the heart pumps the equivalent of the entire blood volume each minute. In other words, each minute the right ventricle normally pumps 5 litres of blood through the lungs, and the left ventricle pumps 5 litres through the systemic circulation. At this rate, each half of the heart would pump about 2.5 million litres of blood in just one year. Yet this is only the resting cardiac output! During exercise, cardiac output can increase to 20–25 L/min, and outputs as high as 40 L/min have been reported in elite endurance athletes. The difference between the cardiac output at rest and at maximum exercise is called the **cardiac reserve**.

How can cardiac output vary so tremendously, depending on the demands of the body? You can readily answer this question by thinking about how your own heart pounds rapidly (increased heart rate) and forcefully (increased stroke volume) when you engage in strenuous physical activities (need for increased cardiac output). Thus regulation of cardiac output depends on the control of both heart rate and stroke volume, topics that we discuss next.

Heart rate

The SA node is normally the pacemaker of the heart, because it has the fastest spontaneous rate of depolarization to threshold. Recall that this automatic, gradual reduction of membrane

potential between beats is due to a complex interplay of ion movements involving the inward movement of potassium and sodium through the I_f channel and an increased Ca^{2+} permeability. When the SA node reaches threshold, an action potential is initiated that spreads throughout the heart, inducing the heart to contract, that is, have a heartbeat. This happens about 70 times per minute, setting the average heart rate at 70 beats per minute.

The heart is innervated by both divisions of the autonomic nervous system, which can modify the rate (as well as the strength) of contraction, even though nervous stimulation is not required to initiate contraction. The parasympathetic nerve to the heart, the vagus nerve, primarily supplies the atrium, especially the SA and AV nodes. Parasympathetic innervation of the ventricles is sparse. The cardiac sympathetic nerves also supply the atria, including the SA and AV nodes, and richly innervate the ventricles as well.

Both the parasympathetic and sympathetic nervous system bring about their effects on the heart by altering the activity of the cyclic AMP second-messenger system in the innervated cardiac cells. Acetylcholine released from the vagus nerve binds to a muscarinic receptor and is coupled to an inhibitory G protein that reduces activity of the cyclic AMP pathway (p. 192) and (p. 217). By contrast, the sympathetic neurotransmitter norepinephrine binds with a β_1 adrenergic receptor and is coupled to a stimulatory G protein that accelerates the cyclic AMP pathway in the target cells (p. 193).

Let's examine the specific effects that parasympathetic and sympathetic stimulation have on the heart (■ Table 8-3).

EFFECT OF PARASYMPATHETIC STIMULATION ON THE HEART

- The parasympathetic nervous system's influence on the SA node is to decrease the heart rate. Acetylcholine released on increased parasympathetic activity increases the permeability

of the SA node to potassium by slowing the closure of K^+ channels. As a result, the rate at which spontaneous action potentials are initiated is reduced through a twofold effect:

1. Enhanced K^+ permeability hyperpolarizes the SA node membrane because more positive potassium ions leave than normal, making the inside even more negative. Because the resting potential starts even farther away from threshold, it takes longer to reach threshold.
 2. The enhanced K^+ permeability induced by vagal stimulation also opposes I_f current responsible for initiating the gradual depolarization of the membrane to threshold. This countering effect decreases the rate of spontaneous depolarization, prolonging the time required to drift to threshold. Therefore, the SA node reaches threshold and fires less frequently, decreasing the heart rate (► Figure 8-18).
- Parasympathetic influence on the AV node decreases the node's excitability, prolonging transmission of impulses to the ventricles even longer than the usual AV nodal delay. This effect is brought about by increasing K^+ permeability, which hyperpolarizes the membrane, thereby retarding the initiation of excitation in the AV node.
 - Parasympathetic stimulation of the atrial contractile cells shortens the action potential, reducing the slow inward current carried by calcium; that is, the plateau phase is shortened. As a result, atrial contraction is weakened.
 - The parasympathetic system has little effect on ventricular contraction, because of the sparseness of parasympathetic innervation to the ventricles.

Thus, the heart is more "leisurely" under parasympathetic influence. It beats less rapidly, the time between atrial and ventricular contraction is stretched out, and atrial contraction is weaker.

■ **TABLE 8-3** Effects of the Autonomic Nervous System on the Heart and Structures That Influence the Heart

Area Affected	Effect of Parasympathetic Stimulation	Effect of Sympathetic Stimulation
SA Node	Decreases the rate of depolarization to threshold; decreases the heart rate	Increases the rate of depolarization to threshold; increases the heart rate
AV Node	Decreases excitability; increases the AV nodal delay	Increases excitability; decreases the AV nodal delay
Ventricular Conduction Pathway	No effect	Increases excitability; hastens conduction through bundle of His and Purkinje cells
Atrial Muscle	Decreases contractility; weakens contraction	Increases contractility; strengthens contraction
Ventricular Muscle	No effect	Increases contractility; strengthens contraction
Adrenal Medulla (an endocrine gland)	No effect	Promotes adrenomedullary secretion of epinephrine, a hormone that augments the sympathetic nervous system's actions on the heart
Veins	No effect	Increases venous return, which increases the strength of cardiac contraction through the Frank-Starling mechanism

FIGURE 8-18 Autonomic control of SA node activity and heart rate. Parasympathetic stimulation decreases the rate of SA nodal depolarization so that the membrane reaches threshold more slowly and has fewer action potentials, whereas sympathetic stimulation increases the rate of depolarization of the SA node so that the membrane reaches threshold more rapidly and has more frequent action potentials. Because each SA node action potential ultimately leads to a heartbeat, increased parasympathetic activity decreases the heart rate, whereas increased sympathetic activity increases the heart rate.

These actions are appropriate, considering that the parasympathetic system controls heart action in quiet, relaxed situations when the body is not demanding an enhanced cardiac output.

EFFECT OF SYMPATHETIC STIMULATION ON THE HEART

- The sympathetic nervous system, which controls heart action in emergency or exercise situations, when there is a need for greater blood flow, speeds up the heart rate through its effect on the pacemaker tissue. The main effect of sympathetic stimulation on the SA node is to speed up depolarization so that threshold is reached more rapidly. Norepinephrine released from the sympathetic nerve endings enhances the pacemaker currents, reducing the time it normally takes to reach threshold. This swifter drift to threshold under sympathetic influence permits more frequent action potentials and a correspondingly faster heart rate (Figure 8-18, and Table 8-3).
- Sympathetic stimulation of the AV node reduces the AV nodal delay by increasing conduction velocity, presumably by enhancing the slow, inward Ca^{2+} current.

- Similarly, sympathetic stimulation speeds up the spread of the action potential throughout the specialized conduction pathway.
- In the atrial and ventricular contractile cells, both of which have many sympathetic nerve endings, sympathetic stimulation increases contractile strength, so the heart beats more forcefully and squeezes out more blood. This effect is produced by increasing Ca^{2+} permeability, which enhances the slow Ca^{2+} influx and intensifies Ca^{2+} participation in excitation coupling.

The overall effect of sympathetic stimulation on the heart, therefore, is to improve its effectiveness as a pump by increasing heart rate, decreasing the delay between atrial and ventricular contraction, decreasing conduction time throughout the heart, and increasing the force of contraction; that is, sympathetic stimulation revs up the heart.

CONTROL OF HEART RATE

As you can see from the preceding discussion, the parasympathetic and sympathetic effects on heart rate are antagonistic (oppose each other), which is typical of the autonomic nervous system. At any given moment, heart rate is determined largely by the balance between inhibition of the SA node by the vagus nerve and stimulation by the cardiac sympathetic nerves. Under resting conditions, parasympathetic discharge dominates. In fact, if all autonomic nerves to the heart were blocked, the resting heart rate would increase from its average value of 70 beats per minute to about 100 beats per minute, which is the inherent rate of the SA node's spontaneous discharge when not subjected to any nervous influence. (We use 70 beats per minute as the normal rate of SA node discharge because this is the average rate under normal resting conditions when parasympathetic activity dominates.) The heart rate can be altered beyond this resting level in either direction by shifting the balance of autonomic nervous stimulation. Heart rate is speeded up by simultaneously increasing sympathetic and decreasing parasympathetic activity; heart rate is slowed by a concurrent rise in parasympathetic activity and decline in sympathetic activity. In turn, the relative level of activity in these two autonomic branches to the heart is primarily coordinated by the *cardiovascular control centre* in the brain stem.

Although autonomic innervation is the primary means by which heart rate is regulated, other factors affect it as well. The most important is epinephrine, a hormone that on sympathetic stimulation is secreted into the blood from the adrenal medulla and that acts on the heart in a manner similar to norepinephrine (the sympathetic neurotransmitter) to increase heart rate. Epinephrine therefore reinforces the direct effect that the sympathetic nervous system has on the heart.

Stroke volume

The other component besides heart rate that determines cardiac output is stroke volume, the amount of blood pumped out by each ventricle during each beat. Two types of controls influence stroke volume: (1) *intrinsic control* related to the extent

► **FIGURE 8-19** Intrinsic and extrinsic control of stroke volume

of venous return, and (2) *extrinsic control* related to the extent of sympathetic stimulation of the heart. Both factors increase stroke volume by increasing the strength of heart contraction (► Figure 8-19). Let us examine each factor in detail to see how they influence stroke volume.

Increased end-diastolic volume

Intrinsic control of stroke volume, which refers to the heart's inherent ability to vary stroke volume, depends on the direct correlation between end-diastolic volume and stroke volume. As more blood returns to the heart, the heart pumps out more blood per beat, but the relationship is not quite as simple as it might seem, because the heart does not eject all the blood it contains. This intrinsic control depends on the length–tension relationship of cardiac muscle, which is similar to that of skeletal muscle. For skeletal muscle, the resting muscle length is approximately the optimal length (l_o) at which maximal tension can be developed during a subsequent contraction. When the skeletal muscle is longer or shorter than l_o , the subsequent contraction is weaker (see ► Figure 7-17). For cardiac muscle, the resting cardiac muscle fibre length is less than l_o . Therefore, the length of cardiac muscle fibres normally varies

along the ascending limb of the length–tension curve. An increase in cardiac muscle fibre length, by moving closer to l_o , increases the contractile tension of the heart on the following systole (► Figure 8-20).

Unlike in skeletal muscle, the length–tension curve of cardiac muscle normally does not operate at lengths that fall within the region of the descending limb. That is, within physiological limits, cardiac muscle does not get stretched beyond its optimal length to the point that contractile strength diminishes with further stretching.

FRANK-STARLING LAW OF THE HEART

What causes cardiac muscle fibres to vary in length before contraction? Skeletal muscle length can vary before contraction because of the positioning of the skeletal parts to which the muscle is attached, but cardiac muscle is not attached to any bones. The main determinant of cardiac muscle fibre length is the degree of diastolic filling. The greater the diastolic filling, the larger the end-diastolic volume (EDV), and the more the heart is stretched. The more the heart is stretched, the longer the initial cardiac fibre length before contraction. The increased length results in a greater force on the subsequent cardiac contraction, which results in a greater stroke volume. This intrinsic relationship between EDV and stroke volume is known as the **Frank–Starling law of the heart**. Stated simply, the heart normally pumps out during systole the volume of blood returned to it during diastole; increased venous return results in increased stroke volume. In Figure 8-20, assume that EDV increases from point A to point B. You can see that this increase in EDV is accompanied by a corresponding increase in stroke volume from point A¹ to point B¹. The extent of filling is referred to as the

► **FIGURE 8-20** Intrinsic control of stroke volume (Frank–Starling curve). The cardiac muscles fibre's length, which is determined by the extent of venous filling, is normally less than the optimal length for developing maximal tension. Therefore, an increase in end-diastolic volume (i.e., an increase in venous return), accomplished by moving the cardiac muscle fibre length closer to optimal length, increases the contractile tension of the fibres on the next systole. A stronger contraction squeezes out more blood. In this way, as more blood is returned to the heart and the end-diastolic volume increases, the heart automatically pumps out a correspondingly larger stroke volume.

preload, because it is the workload imposed on the heart before contraction begins.

ADVANTAGES OF THE CARDIAC LENGTH-TENSION RELATIONSHIP

The built-in relationship that matches stroke volume with venous return has two important advantages. First, one of the most important functions of this intrinsic mechanism is the equalizing of output between the right and left sides of the heart so that blood pumped out by the heart is equally distributed between the pulmonary and systemic circulation. If, for example, the right side of the heart ejects a larger stroke volume, more blood enters the pulmonary circulation, so venous return to the left side of the heart increases accordingly. The increased EDV of the left side of the heart causes it to contract more forcefully, so it too pumps out a larger stroke volume. In this way, output of the two ventricular chambers is kept equal. If such equalization did not happen, too much blood would be dammed up in the venous system in front of the ventricle with the lower output.

Second, when a larger cardiac output is needed, such as during exercise, venous return is increased through action of the sympathetic nervous system and other mechanisms (see Chapter 9). The resulting increase in EDV automatically increases stroke volume correspondingly. Because exercise also increases heart rate, these two factors act together to increase the cardiac output (cardiac output = stroke volume $\times$ heart rate), and therefore more blood can be delivered to the exercising muscles.

MECHANISM OF THE CARDIAC LENGTH-TENSION RELATIONSHIP

Although the length-tension relationship in cardiac muscle fibres depends to a degree on the extent of overlap of thick and thin filaments, the key factor relating cardiac muscle fibre length to tension development is the dependence of myofilament Ca^{2+} sensitivity on the fibre's length. Specifically, as a cardiac muscle fibre's length increases along the ascending limb of the length-tension curve, the lateral spacing between adjacent thick and thin filaments is reduced. Stated differently, as a cardiac muscle fibre is stretched as a result of greater ventricular filling, its myofilaments are pulled closer together. As a result of this reduction in distance between the thick and thin filaments, more cross-bridge interactions between myosin and actin can take place when Ca^{2+} pulls the troponin-tropomyosin complex away from actin's cross-bridge binding sites; that is, myofilament Ca^{2+} sensitivity increases. Thus, the length-tension relationship in cardiac muscle depends not on muscle fibre length *per se* but on the resultant variations in the lateral spacing between the myosin and actin filaments.

EFFECT OF AFTERLOAD ON STROKE VOLUME

Preload and its effect on EDV have been discussed, but another important factor affects stroke volume—**afterload**, which refers to the forces that the heart is

contracting against. Afterload is a combination of the EDV, the volume of blood the ventricles are contracting on, and also the pressure that the ventricles are contracting against. In general, we consider the pressure to be the greater contributor to afterload.

For example, as discussed in Section 8.4 regarding the cardiac cycle, blood will not flow out of the left ventricle until left ventricular pressure exceeds the aortic pressure (end of C, Figure 8-16). However, in situations when aortic pressure is higher than normal, there is an increased afterload. As a result of this increased afterload, the ventricle must contract against a greater pressure and may not eject as much blood as normal. If EDV increases as a result of this decreased stroke volume then the intrinsic control of contractility will increase the strength of contraction to compensate. However, if EDV does not change then the heart will rely on extrinsic control of stroke volume.

We now shift our attention from intrinsic control to extrinsic control of stroke volume.

Sympathetic stimulation

In addition to intrinsic control, stroke volume is also subject to extrinsic control by factors originating outside the heart, the most important of which are actions of the cardiac sympathetic nerves and epinephrine (see Table 8-3). Sympathetic stimulation and epinephrine enhance the heart's **contractility**, which is the strength of contraction at any given EDV. In other words, on sympathetic stimulation the heart contracts more forcefully and squeezes out a greater percentage of the blood it contains, leading to more complete ejection. This increased contractility is due to the increased Ca^{2+} influx triggered by norepinephrine and epinephrine. The extra cytosolic Ca^{2+} lets the myocardial fibres generate more force through greater cross-bridge cycling than they would without sympathetic influence. Recall that normally, the EDV is 135 mL and the end-systolic

FIGURE 8-21 Effect of sympathetic stimulation on stroke volume. (a) Normal stroke volume. (b) Stroke volume during sympathetic stimulation. (c) Stroke volume with combination of sympathetic stimulation and increased end-diastolic volume

volume (ESV) is 65 mL for a stroke volume of 70 mL (► Figure 8-21a). Another variable associated with EDV and stroke volume is **ejection fraction**, which is the fraction of blood pumped from the left ventricle with each beat of the heart. The ejection fraction is equal to stroke volume divided by EDV. It is typically expressed as a percentage and ranges between 55 and 60 percent during rest, which indicates that 40 percent is still remaining in the left ventricle. Damage to the muscle of the heart (myocardium), such as a myocardial infarction, impairs the heart's ability to eject blood and therefore reduces the ejection fraction. Consequently, the measure of ejection fraction has clinical application for such conditions as heart failure. Under sympathetic influence, for the same EDV of 135 mL, the ESV might be 35 mL and the stroke volume 100 mL (► Figure 8-21b). In effect, sympathetic stimulation shifts the Frank-Starling curve to the left (► Figure 8-22). Depending on the extent of sympathetic stimulation, the curve can be shifted to varying degrees, up to a maximal increase in contractile strength of about 100 percent greater than normal.

Sympathetic stimulation increases stroke volume not only by strengthening cardiac contractility but also by enhancing venous return (► Figure 8-21c). Sympathetic stimulation constricts the veins, and this squeezes more blood forward from the veins to the heart, increasing the EDV and subsequently increasing stroke volume even further.

SUMMARY OF FACTORS AFFECTING STROKE VOLUME AND CARDIAC OUTPUT

The strength of cardiac muscle contraction and, accordingly, the stroke volume can be graded by (1) varying the initial length of the muscle fibres, which in turn depends on the degree of ventricular filling before contraction (intrinsic control); and (2) varying the extent of sympathetic stimulation (extrinsic control) (see Figure 8-19). This is in contrast to gradation of skeletal muscle, in which twitch summation and recruitment of motor

► **FIGURE 8-22** Shift of the Frank-Starling curve to the left by sympathetic stimulation. For the same end-diastolic volume (point A), there is a larger stroke volume (from point B to point C) on sympathetic stimulation as a result of increased contractility of the heart. The Frank-Starling curve is shifted to the left by variable degrees, depending on the extent of sympathetic stimulation.

units produce variable strength of muscle contraction. These mechanisms do not apply to cardiac muscle. Twitch summation is impossible because of the long refractory period. Recruitment of motor units is not possible because the heart muscle cells are arranged into functional syncytia where all contractile cells become excited and contract with every beat, instead of into distinct motor units that can be discretely activated.

All the factors that determine cardiac output by influencing heart rate or stroke volume are summarized in ► Figure 8-23. Note that sympathetic stimulation increases cardiac output by increasing both heart rate and stroke volume. Sympathetic activity to the heart increases, for example, during exercise when the working skeletal muscles need increased delivery of oxygen-laden blood to support their high rate of ATP consumption.

■ Why It Matters High Blood Pressure

When the ventricles contract, in order to force open the semilunar valves, they must generate sufficient pressure to exceed the blood pressure in the major arteries. The arterial blood pressure is called the afterload, because it is the workload imposed on the heart after the contraction has begun. If the arterial blood pressure is chronically elevated (high blood pressure) or if the exit valve is stenotic, the ventricle must generate more pressure to eject blood. For example, instead of generating the normal pressure of 120 mmHg, the ventricular pressure may need to rise as high as 400 mmHg to force blood through a narrowed aortic valve.

The heart may be able to compensate for a sustained increase in afterload by enlarging (through hypertrophy or enlargement of the cardiac muscle fibres). This enables it to contract more forcefully and maintain a normal stroke volume despite an abnormal impediment to ejection. A diseased heart or a heart weakened with age may not be able to compensate completely, however; in that case, heart failure ensues. Even if the heart is initially able to compensate for a chronic increase in afterload, the sustained extra workload placed on the heart can eventually cause pathological changes in the heart that lead to heart failure. In fact, a chronically elevated afterload is one of the two major factors that cause heart failure.

FIGURE 8-23 Control of cardiac output

Clinical Connections

Myocardial infarction causes a decrease in cardiac output, and if this decrease is large enough it can cause death. In fact, many of the symptoms that can be experienced during an acute heart attack are a result of the reflex responses that try to maintain cardiac output.

During acute myocardial infarction, there is a decrease in blood delivery to the heart tissue. Since the heart requires large amounts of ATP, it is forced to shift from aerobic to anaerobic metabolism (p. 24), which is less efficient in generating ATP and leads to impaired contractile function of the heart. This decreased ability of the heart to contract is called systolic dysfunction; this means the ventricle cannot eject as much blood as normal, so stroke volume and thus cardiac output decrease. On top of this, large infarcted areas reduce ventricular compliance—its ability to expand—so during ventricular filling, ventricular pressure increases faster and EDV is decreased. This is called diastolic dysfunction, which reduces cardiac output by shifting the Frank–Starling curve to the left (see Figure 8-20 and assume B is normal and A is after the heart attack).

Next we examine how a failing heart cannot pump out enough blood.

Heart failure

Heart failure is the inability of the cardiac output to keep pace with the body's demands for nutrient supplies and removal of wastes. Either one or both ventricles may progressively weaken and fail. When a failing ventricle cannot pump out all the blood returned to it, the veins behind

the failing ventricle become congested with blood. Heart failure may occur for a variety of reasons, but the two most common are (1) damage to the heart muscle as a result of a heart attack or impaired circulation to the cardiac muscle; and (2) prolonged pumping against a chronically increased afterload, as with a stenotic semilunar valve or a sustained elevation in blood pressure. Recently, researchers D. Warburton, at the University of British Columbia, and M. Hay Kowsky, at the University of Alberta, have made significant contributions to understanding heart failure and to the importance of exercise in positively influencing the quality of life of those with heart failure.

PRIME DEFECT IN HEART FAILURE

The prime defect in heart failure is a decrease in cardiac contractility; that is, weakened cardiac muscle cells contract less effectively. The intrinsic ability of the heart to develop pressure and eject a stroke volume is reduced so that the heart operates on a lower length–tension curve (Figure 8-24a). The Frank–Starling curve shifts downward and to the right such that for a given EDV, a failing heart pumps out a smaller stroke volume than a normal healthy heart.

COMPENSATORY MEASURES FOR HEART FAILURE

In the early stages of heart failure, two major compensatory measures help restore stroke volume to normal. First, sympathetic activity to the heart is increased by reflex, which increases heart contractility toward normal (Figure 8-24b). Sympathetic stimulation can help compensate only for a limited period of time, however, because the heart becomes less responsive to norepinephrine after prolonged exposure, and furthermore, the stores of norepinephrine in the heart's sympathetic nerve terminals becomes depleted. Second, when cardiac output is reduced, the kidneys, in a compensatory attempt to improve their reduced blood flow, retain extra salt and water in the body during urine formation, to expand the blood volume. The increase in circulating blood volume increases the EDV. The resultant stretching of the cardiac muscle fibres enables the weakened heart to pump out a normal stroke volume (Figure 8-24b). The heart is now pumping out the blood returned to it but is operating at a greater cardiac muscle fibre length.

DECOMPENSATED HEART FAILURE

As the disease progresses and heart contractility deteriorates further, the heart reaches a point at which it can no longer pump out a normal stroke volume (i.e., cannot pump out all the blood returned to it) despite compensatory measures. At this point, the heart slips from compensated heart failure into a state of decompensated heart failure. Now the cardiac muscle fibres are stretched to the point that they are operating in the descending limb of the length–tension curve. *Forward failure* occurs as the heart fails to pump an adequate amount of blood forward to the tissues because the stroke volume becomes progressively smaller. *Backward failure* occurs simultaneously as blood that cannot enter and be pumped out by the heart continues to dam up the venous system. The congestion in the venous system is the reason that this condition is sometimes termed **congestive heart failure**.

Left-sided failure has more serious consequences than right-sided failure. Backward failure of the left side leads to pulmonary oedema (excess tissue fluid in the lungs) because blood backs

FIGURE 8-24 Compensated heart failure. (a) Shift of the Frank–Starling curve downward and to the right in a failing heart. Because its contractility is decreased, the failing heart pumps out a smaller stroke volume at the same end-diastolic volume than a normal heart does. (b) Compensations for heart failure. Reflex sympathetic stimulation shifts the Frank–Starling curve of a failing heart to the left, increasing the contractility of the heart toward normal. A compensatory increase in end-diastolic volume as a result of blood volume expansion further increases the strength of contraction of the failing heart. Operating at a longer cardiac muscle fibre length, a compensated failing heart is able to eject a normal stroke volume.

up in the lungs. This fluid accumulation in the lungs reduces exchange of oxygen and carbon dioxide between the air and blood in the lungs, thereby reducing arterial oxygenation and elevating levels of acid-forming carbon dioxide in the blood. In addition, one of the more serious consequences of left-sided forward failure is an inadequate blood flow to the kidneys, which causes a twofold problem. First, vital kidney function is depressed; and second, the kidneys retain even more salt and water in the body during urine formation as they try to expand the plasma volume even further to improve their reduced blood flow. Excessive fluid retention further exacerbates the already existing problems of venous congestion.

Treatment of congestive heart failure therefore includes measures that reduce salt and water retention and increase urinary output as well as drugs that enhance the contractile ability of the weakened heart—digitalis, for example.

OTHER TYPES OF HEART FAILURE

So far, we have discussed the chronic form of heart failure that is caused by the progressive inability of the heart to pump enough blood to satisfy the metabolic needs of the peripheral tissues. However, it is important to note there are other forms of heart failure that are just as life-threatening.

Given that the heart and lungs work in tandem to deliver oxygen throughout the body, it is clear that when the lungs are not functioning properly there can be an effect on the function of the heart. This is what is observed in lung disorders such as chronic obstructive pulmonary disease, emphysema, and pulmonary hypertension. When the lung is diseased, blood flow through the pulmonary circulation is compromised such that the right side of the heart has to pump harder to maintain blood flow. Eventually, as seen with the left ventricle in congestive heart failure, the right side of the heart will undergo hypertrophy and eventually fail. This form of right-side heart failure is called **cor pulmonale** or, more commonly, pulmonary heart disease.

Until recently, most of the research for heart failure has focused on chronic heart failure, but it is now recognized that **acute heart failure** is just as important. The main difference in these forms is that acute heart failure progresses rapidly (over days to weeks) such that the heart does not have time to try to compensate for the increased cardiac demands. Acute heart failure has many causes but always relates to something that has caused a relatively sudden inability of the heart to pump blood normally. One example of this could be in a person who has suffered an acute myocardial infarction. In such a case, if a significant part of the ventricular muscle becomes damaged, the ability of the heart to pump blood is reduced. Another example is pulmonary oedema. Similar to what is seen with

cor pulmonale, pulmonary oedema causes an increase in pulmonary pressures and can rapidly affect right ventricular function.

SYSTOLIC VERSUS DIASTOLIC HEART FAILURE

Increasingly, physicians categorize heart failure as either *systolic failure*, characterized by a decrease in cardiac contractility as just described, or *diastolic failure*, in which the heart has trouble filling. Diastolic failure is a recently recognized problem. With diastolic failure, the ventricles do not fill normally either because the heart muscle does not adequately relax between beats or because the heart muscle stiffens and cannot expand as much as usual. Because of impeded filling, a diastolic failing heart pumps out less blood than it should with each contraction. No drugs are available yet that reliably help the heart relax, so treatment is aimed at relieving symptoms or halting underlying causes of diastolic disease.

In Canada and around the world, heart disease is a leading cause of premature death. Recent developments in myocardial disease (cardiac muscle tissue) have led to the classification of new therapeutic targets, one of which is gene and stem cell therapies for the protection and revival of the myocardium. To date, genetic therapies have been used to treat complex diseases, such as heart failure, ischemia, and other inherited myopathies, in animals. Such progress in this field has been made that in 2013, a clinical trial led by Dr. Duncan Stewart, a cardiologist at the Ottawa Hospital Research Institute, began to study the combined effects of genetically enhanced stem cells on repairing damaged heart muscle following a heart attack.

Check Your Understanding 8.4

1. Indicate the effect (increase or decrease) of parasympathetic stimulation and sympathetic stimulation on heart rate and stroke volume.
2. Draw a graph showing the relationship between end-diastolic volume and stroke volume, according to the Frank–Starling law of the heart.

8.6 | Nourishing the Heart Muscle

Cardiac muscle cells contain an abundance of mitochondria, the oxygen-dependent energy organelles. In fact, up to 40 percent of the cell volume of cardiac muscle cells is occupied by mitochondria, indicative of how much the heart depends on oxygen delivery and aerobic metabolism to generate the energy necessary for contraction. Cardiac muscle also has an abundance of myoglobin, which stores limited amounts of oxygen within the heart for immediate use.

The heart's blood supply

Although all the blood passes through the heart, the heart muscle cannot extract oxygen or nutrients from the blood within its chambers for two reasons. First, the watertight endocardial lining does not permit blood to pass from the chamber into the myocardium. Second, the heart walls are too thick to permit diffusion of oxygen and other supplies from the blood in the chamber to the individual cardiac cells. Therefore, like other tissues of the body, heart muscle must receive blood through blood vessels, specifically via the **coronary circulation**. The coronary arteries branch from the aorta just beyond the aortic valve, and the coronary veins empty into the right atrium.

The heart muscle receives most of its blood supply during diastole. Blood flow to the heart muscle cells is substantially reduced during systole for two reasons. First, the contracting myocardium, especially in the powerful left ventricle, compresses the major branches of the coronary arteries; second, the open aortic valve partially blocks the entrance to the coronary vessels. As a result, most coronary arterial flow (about 70%) occurs during diastole, driven by the aortic blood

pressure, and it declines as aortic pressure drops. Only about 30 percent of coronary arterial flow occurs during systole (► Figure 8-25).

This limited time for coronary blood flow becomes especially important during rapid heart rates, when diastolic time is much reduced. Just when increased demands are placed on the heart to pump more rapidly, it has less time to provide oxygen and nourishment to its own musculature to accomplish the increased workload.

MATCHING OF CORONARY BLOOD FLOW TO HEART MUSCLE'S OXYGEN NEEDS

Under normal circumstances the heart muscle does receive adequate blood flow to support its activities, even during exercise, when the rate of coronary blood flow increases up to five times its resting rate. Let's see how.

Extra blood is delivered to the cardiac cells primarily by vasodilation, or enlargement, of the coronary vessels, which lets more blood flow through them, especially during diastole. The increased coronary blood flow is necessary to meet the heart's increased oxygen requirements because the heart, unlike most other tissues, is unable to remove much additional oxygen from the blood passing through its vessels to support increased metabolic activities. Most other tissues under resting conditions extract only about 25 percent of the oxygen available from the blood flowing through them, leaving a considerable oxygen reserve that can be drawn on when a tissue has increased oxygen needs; that is, the tissue can immediately increase the oxygen available to it by removing a greater percentage of oxygen from the blood passing through it. In contrast, the heart, even under resting conditions, removes up to 65 percent of the oxygen available in the coronary vessels, far more than is withdrawn by other tissues. This leaves little oxygen in reserve in the coronary blood should cardiac oxygen demands increase. Therefore, the primary means by which more oxygen can be made available to the heart muscle is by increasing coronary blood flow.

Coronary blood flow is adjusted primarily in response to changes in the heart's oxygen requirements. Among the proposed links between blood flow and oxygen needs is *adenosine*,

► **FIGURE 8-25** Coronary blood flow. Most coronary blood flow occurs during diastole because the coronary vessels are compressed almost completely during systole.

which is formed from adenosine triphosphate (ATP) during cardiac metabolic activity. Cardiac cells form and release more adenosine when cardiac activity increases and the heart is using more ATP as an energy source and, accordingly, needs more oxygen. The released adenosine, acting as a paracrine (p. 51), induces dilation of the coronary blood vessels, which allows more oxygen-rich blood to flow to the more active cardiac cells to meet their increased oxygen demand (► Figure 8-26). Matching oxygen delivery to oxygen needs is crucial, because heart muscle depends on oxidative processes to generate energy. The heart cannot get enough ATP through anaerobic metabolism.

NUTRIENT SUPPLY TO THE HEART

Although the heart has little ability to support its energy needs by means of anaerobic metabolism and must rely heavily on its oxygen supply, it can tolerate wide variations in its nutrient supply. As fuel sources, the heart primarily uses free fatty acids and, to a lesser extent, glucose and lactate, depending on their availability. Because cardiac muscle is remarkably adaptable and can shift metabolic pathways to use whatever nutrient is available, the primary danger of insufficient coronary blood flow is not fuel shortage but oxygen deficiency.

Atherosclerotic coronary artery disease

The adequacy of coronary blood flow is relative to the heart's oxygen demands at any given moment. In the normal heart, coronary blood flow increases correspondingly as oxygen demands rise. With coronary artery disease, coronary blood flow may not be able to keep pace with rising oxygen needs. The term **coronary artery disease (CAD)** refers to pathological changes within the coronary artery walls that diminish blood flow through these vessels. A given rate of

coronary blood flow may be adequate at rest but insufficient in physical exertion or other stressful situations.

Complications of CAD, including heart attacks, make it the single leading cause of death in Canada. CAD is the underlying cause of about 32 percent of all deaths in this country. CAD can cause myocardial ischemia and possibly lead to acute myocardial infarction by three mechanisms: (1) profound vascular spasm of the coronary arteries, (2) formation of atherosclerotic plaques, and (3) thromboembolism. We will discuss each in turn.

VASCULAR SPASM

Vascular spasm is an abnormal spastic constriction that transiently narrows the coronary vessels. Vascular spasms are associated with the early stages of CAD and are most often triggered by exposure to cold, physical exertion, or anxiety. The condition is reversible and usually does not last long enough to damage the cardiac muscle.

When too little oxygen is available in the coronary vessels, the endothelium (blood vessel lining) releases *platelet-activating factor (PAF)*. PAF, which exerts a variety of actions, was named for its first discovered effect, activating platelets. Among its other effects, PAF, once released from the endothelium, diffuses to the underlying vascular smooth muscle and causes it to contract, bringing about vascular spasm.

DEVELOPMENT OF ATHEROSCLEROSIS

Atherosclerosis is a progressive, degenerative arterial disease that gradually leads to occlusion (blockage) of affected vessels, reducing blood flow through them. Atherosclerosis is characterized by plaques forming beneath the vessel lining within arterial walls. An **atherosclerotic plaque** consists of a lipid-rich core covered by an abnormal overgrowth of smooth muscle cells, topped off by a collagen-rich connective tissue cap. As plaque forms, it bulges into the vessel lumen (► Figure 8-27).

Although not all the contributing factors have been identified, in recent years investigators have sorted out the following complex sequence of events in the gradual development of atherosclerosis:

1. Atherosclerosis starts with injury to the blood vessel wall, which triggers an *inflammatory response* that sets the stage for plaque buildup. Normally, inflammation is a protective response that fights infection and promotes repair of damaged tissue (p. 466). However, when the cause of the injury persists within the vessel wall, the sustained, low-grade inflammatory response over a course of decades can insidiously lead to arterial plaque formation and heart disease. Plaque formation likely has many causes. Suspected artery-abusing agents that may set off the vascular inflammatory response include oxidized cholesterol, free radicals, high blood pressure, homocysteine, chemicals released from fat cells, or even bacteria and viruses that damage blood vessel

► FIGURE 8-26 Matching of coronary blood flow to the oxygen need of cardiac muscle cells

► **FIGURE 8-27 Atherosclerotic plaque.** (a) Schematic representation of the components of a plaque. (b) Photomicrograph of a severe atherosclerotic plaque in a coronary vessel

walls. The most common triggering agent appears to be oxidized cholesterol. (For a further discussion of the role of cholesterol and other factors in the development of atherosclerosis, see Concepts, Challenges, and Controversies.)

- Typically, the initial stage of atherosclerosis is characterized by the accumulation beneath the endothelium of excessive amounts of *low-density lipoprotein (LDL)*, the so-called bad cholesterol, in combination with a protein carrier. As LDL accumulates within the vessel wall, this cholesterol product becomes oxidized, primarily by oxidative wastes produced by the blood vessel cells. These wastes are *free radicals*—very unstable electron-deficient

particles that are highly reactive. Antioxidant vitamins that prevent LDL oxidation, such as *vitamin E*, *vitamin C*, and *beta-carotene*, have been shown to slow plaque deposition.

- In response to the presence of oxidized LDL and/or other irritants, the endothelial cells produce chemicals that attract *monocytes*, a type of white blood cell, to the site. These immune cells trigger a local inflammatory response.
- Once they leave the blood and enter the vessel wall, monocytes settle down permanently, enlarge, and become large phagocytic cells called *macrophages*. Macrophages voraciously phagocytose (p. 48) the oxidized LDL until these cells become so packed with fatty droplets that they appear foamy under a microscope. Now called *foam cells*, these greatly engorged macrophages accumulate beneath the vessel lining and form a visible *fatty streak*, the earliest form of an atherosclerotic plaque.
- The earliest stage of plaque formation is characterized by accumulation beneath the endothelium of a cholesterol-rich deposit. The disease progresses as smooth muscle cells within the blood vessel wall migrate from the muscular layer of the blood vessel to a position on top of the lipid accumulation, just beneath the endothelium. This migration is triggered by chemicals released at the inflammatory site. At their new location, the smooth muscle cells continue to divide and enlarge, producing *atheromas*, which are benign (non-cancerous) tumours of smooth muscle cells within the blood vessel walls. Together the lipid-rich core and overlying smooth muscle form a maturing plaque.
- As it continues to develop, the plaque progressively bulges into the lumen of the vessel. The protruding plaque narrows the opening through which blood can flow.
- Further contributing to vessel narrowing, oxidized LDL inhibits release of *nitric oxide* from the endothelial cells. Nitric oxide is a local chemical messenger that relaxes the underlying layer of normal smooth muscle cells within the vessel wall. Relaxation of these smooth muscle cells dilates the vessel. Because of reduced nitric oxide release, vessels damaged by developing plaques cannot dilate as readily as normal.
- A thickening plaque also interferes with nutrient exchange for cells located within the involved arterial wall, leading to degeneration of the wall in the vicinity of the plaque. The damaged area is invaded by *fibroblasts* (scar-forming cells), which form a connective tissue cap over the plaque. (The term *sclerosis* means “excessive growth of fibrous connective tissue”—hence, the term *atherosclerosis* for this condition that is characterized by atheromas and sclerosis, along with abnormal lipid accumulation.)
- In the later stages of the disease, calcium often precipitates in the plaque. A vessel so afflicted becomes hard and cannot distend easily.

Atherosclerosis: Cholesterol and Beyond

THE CAUSE OF ATHEROSCLEROSIS IS STILL NOT ENTIRELY CLEAR. Certain high-risk factors have been associated with an increased incidence of atherosclerosis and coronary heart disease. Included among them are genetic predisposition, obesity, advanced age, smoking, hypertension, lack of exercise, high blood concentrations of C-reactive protein, elevated levels of homocysteine, infectious agents, and, most notoriously, elevated cholesterol levels in the blood.

Sources of Cholesterol

There are two sources of cholesterol for the body: (1) dietary intake of cholesterol—animal products, such as egg yolk, red meats, and butter are especially rich in this lipid (animal fats contain cholesterol, whereas plant fats typically do not); and (2) manufacture of cholesterol by cells, especially liver cells.

Good versus Bad Cholesterol

Actually, it is not the total blood cholesterol level but the amount of cholesterol bound to various plasma protein carriers that is most important with regard to the risk of developing atherosclerotic heart disease. Because cholesterol is a lipid, it is not very soluble in blood. Most cholesterol in the blood is attached to specific plasma protein carriers in the form of lipoprotein complexes, which are soluble in blood. The three major lipoproteins are named for their density of protein as compared with lipid: (1) **high-density lipoproteins (HDL)**, which contain the most protein and least cholesterol; (2) **low-density lipoproteins (LDL)**, which have less protein and more cholesterol; and (3) **very-low-density lipoproteins (VLDL)**, which have the least protein and most lipid, but the lipid they carry is neutral fat, not cholesterol.

Cholesterol carried in LDL complexes has been termed *bad cholesterol*, because cholesterol is transported to the cells, including those lining the blood vessel walls, by LDL. The propensity toward developing atherosclerosis substantially increases with elevated levels of LDL. The presence of oxidized LDL within an arterial wall is a major trigger for the inflammatory process that leads to the development of atherosclerotic plaques (p. 375).

In contrast, cholesterol carried in HDL complexes has been dubbed *good cholesterol*, because HDL removes cholesterol from the cells and transports it to the liver for partial elimination from the body. Not only does HDL help remove excess cholesterol from the tissues, it also protects by inhibiting oxidation of LDL. The risk of atherosclerosis is inversely related to the concentration of HDL in the blood; that is, elevated levels of HDL are associated with a low incidence of atherosclerotic heart disease.

Some other factors known to influence atherosclerotic risk can be related to HDL levels; for example, cigarette smoking lowers HDL, whereas regular exercise raises HDL.

Cholesterol Uptake by Cells

Unlike most lipids, cholesterol is not used as metabolic fuel by cells. Instead, it serves as an essential component of plasma membranes. In addition, a few special cell types use cholesterol as a precursor for the synthesis of secretory products, such as steroid hormones and bile salts. Although most cells can synthesize some of the cholesterol needed for their own plasma membranes, they cannot manufacture sufficient amounts and therefore must rely on supplemental cholesterol being delivered by the blood.

Cells accomplish cholesterol uptake from the blood by synthesizing receptor proteins specifically capable of binding LDL and inserting these receptors into the plasma membrane. When an LDL particle binds to one of the membrane receptors, the cell engulfs the particle by receptor-mediated endocytosis, receptor and all (p. 48). Within the cell, lysosomal enzymes break down the LDL to free the cholesterol, making it available to the cell for synthesis of new cellular membrane. The LDL receptor, which is also freed within the cell, is recycled back to the surface membrane.

If too much free cholesterol accumulates in the cell, there is a shut-down of both the synthesis of LDL receptor proteins (so that less cholesterol is taken up) and the cell's own cholesterol synthesis (so that less new cholesterol is made). Faced with a cholesterol shortage, in contrast, the cell makes more LDL receptors so that it can engulf more cholesterol from the blood.

Maintenance of Blood Cholesterol Level and Cholesterol Metabolism

The maintenance of a blood-borne cholesterol supply to the cells involves an interaction between dietary cholesterol and the synthesis of cholesterol by the liver. When the amount of dietary cholesterol is increased, hepatic (liver) synthesis of cholesterol is turned off because cholesterol in the blood directly inhibits a hepatic enzyme essential for cholesterol synthesis. Therefore, as more cholesterol is ingested, less is produced by the liver. Conversely, when cholesterol intake from food is reduced, the liver synthesizes more of this lipid because the inhibitory effect of cholesterol on the crucial hepatic enzyme is removed. In this way, the blood concentration of cholesterol is maintained at a fairly constant level despite changes in cholesterol intake; thus, it is difficult to significantly reduce cholesterol levels in the blood by decreasing cholesterol intake.

HDL transports cholesterol to the liver. The liver secretes cholesterol as well as cholesterol-derived bile salts into the bile. Bile enters the

intestinal tract, where bile salts participate in the digestive process. Most of the secreted cholesterol and bile salts are subsequently reabsorbed from the intestine into the blood to be recycled to the liver. However, the cholesterol and bile salts not reclaimed by absorption are eliminated in the feces and lost from the body.

Consequently, the liver has a primary role in determining total blood cholesterol levels, and the interplay between LDL and HDL determines the traffic flow of cholesterol between the liver and the other cells. Whenever these mechanisms are altered, blood cholesterol levels may be affected in such a way as to influence the individual's predisposition to atherosclerosis.

Varying the intake of dietary fatty acids may alter total blood cholesterol levels by influencing one or more of the mechanisms involved in cholesterol balance. The blood cholesterol level tends to be raised by ingesting saturated fatty acids found predominantly in animal fats, because these fatty acids stimulate cholesterol synthesis and inhibit its conversion to bile salts. In contrast, ingesting polyunsaturated fatty acids, the predominant fatty acids of most plants, tends to reduce blood cholesterol levels by enhancing elimination of both cholesterol and cholesterol-derived bile salts in the feces.

The treatment of elevated cholesterol has been met with moderate success. In 2008, Dr. Trisha R. Joy at the University of Western Ontario discussed the potential treatment of high cholesterol through increasing HDL (the good cholesterol), which helps remove cholesterol from the body. However, clinical trials have indicated that increasing circulating HDL as a treatment for cardiovascular disease may not be as promising as first thought. The functional quality of HDL may be more important than the circulating quantity. Thus, more research is required.

Other Risk Factors besides Cholesterol

Despite the strong links between cholesterol and heart disease, over half of all patients with heart attacks have a normal cholesterol profile and no other well-established risk factors. Clearly, other factors are involved in the development of coronary artery disease in these people. These same factors may also contribute to development of atherosclerosis in people with unfavourable cholesterol levels. The following are among the leading other possible risk factors:

- Elevated blood levels of the amino acid **homocysteine** have recently been implicated as a strong predictor for heart disease, independent of the person's cholesterol/lipid profile. Homocysteine is formed as an intermediate product during metabolism of the essential dietary amino acid *methionine*. Investigators believe homocysteine contributes to atherosclerosis by promoting

proliferation of vascular smooth muscle cells, an early step in development of this artery-clogging condition. Furthermore, homocysteine appears to damage endothelial cells and may cause oxidation of LDL, both of which can contribute to plaque formation. Three B vitamins—*folic acid*, *vitamin B₁₂*, and *vitamin B₆*—all play key roles in pathways that clear homocysteine from the blood. Therefore, these B *vitamins* are all needed to keep blood homocysteine at safe levels.

- Inflammation has also been implicated in the development of atherosclerotic plaques as people with elevated levels of **C-reactive protein**, a blood-borne marker of inflammation, have a higher risk for developing coronary artery disease. In one study, people with a high level of C-reactive protein in their blood were three times more likely to have a heart attack over the next 10 years than those with a low level of this inflammatory protein. Because inflammation plays a crucial role in the development of atherosclerosis, anti-inflammatory drugs, such as Aspirin, help prevent heart attacks. Furthermore, Aspirin protects against heart attacks through its role in inhibiting clot formation.
- Accumulating data suggest that an infectious agent may be the underlying culprit in a significant number of cases of atherosclerotic disease. Among the leading suspects are respiratory infection—causing *Chlamydia pneumoniae*, cold sore—causing *herpes virus*, and gum disease—causing bacteria. Importantly, if a link between infections and coronary artery disease can be confirmed, antibiotics may be added to the regimen of heart disease prevention strategies.

As you can see, the relationship between atherosclerosis, cholesterol, and other factors is far from clear. Much research on this complex disease is currently in progress, because the incidence of atherosclerosis is so high and its consequences are potentially fatal.

THROMBOEMBOLISM AND OTHER COMPLICATIONS OF ATHEROSCLEROSIS

Atherosclerosis attacks arteries throughout the body, but the most serious consequences involve damage to the vessels of the brain and heart. In the brain, atherosclerosis is the prime cause of strokes, whereas in the heart it brings about myocardial ischemia and its complications. The following are potential complications of coronary atherosclerosis:

- **Angina pectoris.** Gradual enlargement of a protruding plaque continues to narrow the vessel lumen and progressively diminishes coronary blood flow, triggering increasingly frequent bouts of transient myocardial ischemia as the ability to match blood flow with cardiac oxygen needs becomes more limited. Although the heart cannot normally be “felt,” pain is associated with myocardial ischemia. Such cardiac pain, known as **angina pectoris** (pain of the chest), can be felt beneath the sternum and is often referred to (appears to come from) the left shoulder and down the left arm. The symptoms of angina pectoris recur whenever cardiac oxygen demands become too great in relation to the coronary blood flow—for example, during exertion or emotional stress. The pain is thought to result from stimulation of cardiac nerve endings by the accumulation of lactic acid when the heart shifts to its limited ability to perform anaerobic metabolism. The ischemia associated with the characteristically brief angina attacks is usually temporary and reversible and can be relieved by rest, taking vasodilator drugs, such as *nitroglycerin*, or both. Nitroglycerin brings about coronary vasodilation by being metabolically converted to nitric oxide, which in turn relaxes the vascular smooth muscle.
- **Thromboembolism.** The enlarging atherosclerotic plaque can break through the weakened endothelial lining that covers it, exposing blood to the underlying collagen in the collagen-rich connective tissue cap of the plaque. Foam cells release chemicals that can weaken the fibrous cap of a plaque by breaking down the connective tissue fibres. Plaques with thick fibrous caps are considered stable, because they are not likely to rupture. However, plaques with thinner fibrous caps are unstable, because they are likely to rupture and trigger clot formation. Blood platelets (formed elements of the blood involved in plugging vessel defects and in clot formation) normally do not adhere to smooth, healthy vessel linings. However, when platelets contact collagen at the site of vessel damage, they stick to the site and help promote the formation of a blood clot. Furthermore, foam cells produce a

potent clot promoter. Such an abnormal clot attached to a vessel wall is called a **thrombus**. The thrombus may enlarge gradually until it completely blocks the vessel at that site, or the continued flow of blood past the thrombus may break it loose. As it heads downstream, such a freely floating clot, or **embolus**, may completely plug a smaller vessel (▶ Figure 8-28). Thus, through **thromboembolism**, atherosclerosis can result in a gradual or sudden occlusion of a coronary vessel (or any other vessel).

- **Heart attack.** When a coronary vessel is completely plugged, the cardiac tissue served by the vessel soon dies from oxygen deprivation, and a heart attack occurs, unless the area can be supplied with blood from nearby vessels. Sometimes a deprived area is lucky enough to receive blood from more than one pathway. **Collateral circulation** exists when small terminal branches from adjacent blood vessels nourish the same area. These accessory vessels cannot develop suddenly after an abrupt blockage but may be lifesaving if already developed. Such alternative vascular pathways often develop over a period of time when an atherosclerotic constriction progresses slowly, or they may be induced by sustained demands on the heart through regular aerobic exercise.

In the absence of collateral circulation, the extent of the damaged area during a heart attack depends on the size of the blocked vessel: the larger the vessel occluded, the greater the area deprived of blood supply. As ▶ Figure 8-29 illustrates, a blockage at point A in the coronary circulation would cause more extensive damage than would a blockage at point B. Because there are only two major coronary arteries, complete blockage of either one of these main branches results in extensive myocardial damage. Left coronary artery blockage is most devastating because this vessel supplies blood to 85 percent of the cardiac tissue.

A heart attack has four possible outcomes: immediate death, delayed death from complications, full functional recovery, or recovery with impaired function (▶ Table 8-4).

▶ **FIGURE 8-28** Consequences of thromboembolism. (a) A thrombus may enlarge gradually until it completely occludes the vessel at that site. (b) A thrombus may break loose from its attachment, forming an embolus that may completely occlude a smaller vessel downstream. (c) Scanning electron microscope of a vessel completely occluded by a thromboembolic lesion

► **FIGURE 8-29** Extent of myocardial damage as a function of the size of the occluded vessel

Clinical Connections

Debbie's blockage is represented by point A in Figure 8-29, which means that she likely had an extensive area of myocardial damage. She underwent a coronary artery bypass graft that allowed blood to flow around the blockage, but by then most of the damage was irreversible. For Debbie to survive, her heart must undergo changes somewhat similar to those described for heart failure (p. 371). The surviving ventricular tissues will undergo hypertrophy to compensate for its decreased ability to contract. However, if not enough compensation occurs she will suffer heart failure and die.

Chapter in Perspective: Focus on Homeostasis

Survival depends on continual delivery of needed supplies to all body cells and ongoing removal of wastes generated by the cells. Furthermore, regulatory chemical messengers,

such as hormones, must be transported from their production site to their action site, where they control a variety of activities, most of which are directed toward maintaining a stable internal environment. Finally, to maintain normal body temperature, excess heat produced during muscle contraction must be carried to the skin where the heat can be lost from the body surface.

The circulatory system contributes to homeostasis by serving as the body's transport system. It provides a way to rapidly move materials from one part of the body to another. Without the circulatory system, materials would not get where they need to go to support life-sustaining activities nearly rapidly enough. For example, oxygen would take months to years to diffuse from the body surface to internal organs, yet through the heart's swift pumping action the blood can pick up and deliver oxygen and other substances to all the cells in a few seconds.

The heart serves as a dual pump to continuously circulate blood between the lungs, where oxygen is picked up, and the other body tissues, which use oxygen to support their energy-generating chemical reactions. As blood is pumped through the various tissues, other substances besides oxygen are also exchanged between the blood and tissues. For example, the blood picks up nutrients as it flows through the digestive organs, and other tissues remove nutrients from the blood as it flows through them. Even excess heat is transported by the blood from exercising muscles to the skin surface, where it is lost to the external environment.

Although all the body tissues constantly depend on the life-supporting blood flow provided to them by the heart, the heart itself is quite an independent organ. It can take care of many of its own needs without any outside influence. Contraction of this muscular organ is self-generated through a carefully orchestrated interplay of changing ionic permeabilities. Local mechanisms within the heart ensure that blood flow to the cardiac muscle normally meets the heart's need for oxygen. In addition, the heart has built-in capabilities to vary its strength of contraction, depending on the amount of blood returned to it. The heart does not act entirely autonomously, however. It is innervated by the autonomic nervous system and is influenced by the hormone epinephrine, both of which can vary heart rate and contractility, depending on the body's needs for blood delivery. Furthermore, as with all tissues, the cells that make up the heart depend on the other body systems to maintain a stable internal environment in which they can survive and function.

■ **TABLE 8-4** Possible Outcomes of Acute Myocardial Infarction (Heart Attack)

Immediate Death

Acute cardiac failure occurring because the heart is too weak to pump effectively to support the body tissues

Fatal ventricular fibrillation brought about by damage to the specialized conducting tissue occurring because the weakened heart is deprived of oxygen

Delayed Death from Complications

Fatal rupture of the dead, degenerating area of the heart wall

Slowly progressing congestive heart failure where the heart becomes unable to pump out all the blood returned to it

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-43)

1. Adjacent cardiac muscle cells are joined end to end at specialized structures known as _____, which contain two types of membrane junctions: _____ and _____.
2. _____ is an abnormally slow heart rate, whereas _____ is a rapid heart rate.
3. The link that coordinates coronary blood flow with myocardial oxygen needs is _____.
4. The left ventricle is a stronger pump than the right ventricle because more blood is needed to supply the body tissues than to supply the lungs. (*True or false?*)

5. The heart lies in the left half of the thoracic cavity. (*True or false?*)
6. The only point of electrical contact between the atria and ventricles is the fibrous skeletal rings. (*True or false?*)
7. The atria and ventricles each act as a functional syncytium. (*True or false?*)
8. What is the sequence of cardiac excitation?
 - a. SA node → AV node → atrial myocardium → bundle of His → Purkinje fibres → ventricular myocardium.
 - b. SA node → atrial myocardium → AV node → bundle of His → ventricular myocardium → Purkinje fibres.
 - c. SA node → atrial myocardium → ventricular myocardium → AV node → bundle of His → Purkinje fibres.
 - d. SA node → atrial myocardium → AV node → bundle of His → Purkinje fibres → ventricular myocardium.
9. What percentage of ventricular filling is normally accomplished before atrial contraction begins?
 - a. 0 percent
 - b. 20 percent
 - c. 50 percent
 - d. 80 percent
 - e. 100 percent
10. What results from sympathetic stimulation of the heart?
 - a. decreases in the heart rate
 - b. increases in the contractility of the heart muscle
 - c. shifts in the Frank–Starling curve to the right
 - d. increases in the AV node delay
11. Match the following:

_____ 1. receives O ₂ -poor blood from venae cavae	(a) AV valves
_____ 2. prevent backflow of blood from the ventricles to the atria	(b) semilunar valves
_____ 3. pumps O ₂ -rich blood into aorta	(c) right ventricle
_____ 4. prevent backflow of blood from the arteries into the ventricles	(d) left ventricle
_____ 5. pumps O ₂ -poor blood into the pulmonary artery	(e) right atrium
12. Circle the correct choice in each instance to complete the statement: The first heart sound is associated with closing of the (*AV/semilunar*) valves and signals the onset of (*systole/diastole*), whereas the second heart sound is associated with closing of the (*AV/semilunar*) valves and signals the onset of (*systole/diastole*).
13. Circle the correct choice in each instance to complete the statements: During ventricular filling, ventricular pressure must be (*greater than/less than*) atrial pressure, whereas during ventricular ejection, ventricular pressure must be (*greater than/less than*) aortic pressure. Atrial pressure is always (*greater than/less than*) aortic pressure. During isovolumetric ventricular contraction and relaxation, ventricular pressure is (*greater than/less than*) atrial pressure and (*greater than/less than*) aortic pressure.

Written Questions

1. What are the three basic components of the circulatory system?
2. Trace a drop of blood through one complete circuit of the circulatory system.
3. Describe the location and function of the four heart valves. What keeps each of these valves from everting?
4. What are the three layers of the heart wall? Describe the distinguishing features of the structure and arrangement of cardiac muscle cells. What are the two specialized types of cardiac muscle cells?
5. Why is the SA node the pacemaker of the heart?
6. Describe the normal spread of cardiac excitation. What is the significance of the AV nodal delay? Why is the ventricular conduction system important?
7. Compare the changes in membrane potential associated with an action potential in a nodal pacemaker cell with those in a myocardial contractile cell. What is responsible for the plateau phase?
8. Why is tetanus of cardiac muscle impossible? Why is this inability advantageous?
9. Draw and label the waveforms of a normal ECG. What electrical event does each component of the ECG represent?
10. Describe the mechanical events (i.e., pressure changes, volume changes, valve activity, and heart sounds) of the cardiac cycle. Correlate the mechanical events of the cardiac cycle with the changes in electrical activity.
11. Distinguish between a stenotic and an insufficient valve.
12. Define the following: *end-diastolic volume*, *end-systolic volume*, *stroke volume*, *heart rate*, *cardiac output*, and *cardiac reserve*.
13. Discuss autonomic nervous system control of heart rate.
14. Describe the intrinsic and extrinsic control of stroke volume.
15. How is the heart muscle provided with blood? Why does the heart receive most of its own blood supply during diastole?
16. What are the pathological changes and consequences of coronary artery disease?
17. Discuss the sources, transport, and elimination of cholesterol in the body. Distinguish between “good” cholesterol and “bad” cholesterol.

Quantitative Exercises (Solutions in Appendix E, p. A-43)

1. During heavy exercise, the cardiac output of a trained athlete may increase to 40 L/min. If stroke volume could not increase above the normal value of 70 mL, what heart rate would be necessary to achieve this cardiac output? Is such a heart rate physiologically possible?
2. How much blood remains in the heart after systole if the stroke volume is 85 mL and the end-diastolic volume is 125 mL?

POINTS TO PONDER

(Explanations in Appendix E, p. A-44)

1. The stroke volume ejected on the next heartbeat after a premature ventricular contraction (PVC) is usually larger than normal. Can you explain why? (*Hint:* At a given heart rate, the interval between a PVC and the next normal beat is longer than the interval between two normal beats.)
2. Trained athletes usually have lower resting heart rates than normal (e.g., 50 beats/min in an athlete compared with 70 beats/min in a sedentary individual). Considering that the resting cardiac output is 5000 mL/min in both trained athletes and sedentary people, how are trained athletes able to generate the same cardiac output in the face of a reduced heart rate?
3. During fetal life, because of the tremendous resistance offered by the collapsed, nonfunctioning lungs, the pressures in the right half of the heart and pulmonary circulation are higher than in the left half of the heart and systemic circulation, a situation that reverses after birth. Also in the fetus, a vessel called the *ductus arteriosus* connects the pulmonary artery and aorta as these major vessels both leave the heart. The blood pumped out by the heart into the pulmonary circulation is shunted from the pulmonary artery into the aorta through the ductus arteriosus, bypassing the nonfunctional lungs. What force is driving blood to flow in this direction through the ductus arteriosus?
4. At birth, the ductus arteriosus normally collapses and eventually degenerates into a thin, ligamentous strand. On occasion, this fetal bypass fails to close properly at birth, leading to a *patent* (open) *ductus arteriosus*. In what direction would blood flow through a patent ductus arteriosus? What possible outcomes do you predict might occur as a result of this blood flow?
5. Through what regulatory mechanisms can a transplanted heart, which does not have any innervation, adjust cardiac output to meet the body's changing needs?
6. There are two branches of the bundle of His, the right and left bundle branches, each of which travels down its respective side of the ventricular septum (see Figure 8-8). Occasionally, conduction through one of these branches becomes blocked (so-called bundle-branch block). In this case, the wave of excitation spreads out from the terminals of the intact branch and eventually depolarizes the whole ventricle, but the normally stimulated ventricle completely depolarizes a considerable time before the ventricle on the side of the defective bundle branch. For example, if the left bundle branch is blocked, the right ventricle will be completely depolarized two to three times more rapidly than the left ventricle. How would this defect affect the heart sounds?

8

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-44)

1. In a physical exam, Rachel B.'s heart rate was rapid and very irregular. Furthermore, her heart rate, determined directly by listening to her heart with a stethoscope, exceeded the pulse rate taken concurrently at her wrist. No definite P waves could be detected on Rachel's ECG. The QRS complexes were normal in shape but occurred sporadically. Given these findings, what is the most likely diagnosis of Rachel's condition? Explain why the condition is characterized by a rapid, irregular heartbeat. Would cardiac output be seriously impaired by this condition? Why or why not? What accounts for the pulse deficit?

Vascular Physiology

Body systems maintain homeostasis

Vascular system

Cells make up body systems

Homeostasis

The circulatory system contributes to homeostasis by transporting O_2 , CO_2 , wastes, electrolytes, and hormones from one part of the body to another.

Homeostasis is essential for survival of cells

Scanning electron micrograph of an artery

© Science Photo Library/Alamy

The circulatory system contributes to homeostasis by serving as the body's transport system. The blood vessels transport and distribute blood pumped through them by the heart to meet the body's needs for oxygen and nutrient delivery, waste removal, and hormonal signalling. The highly elastic arteries transport blood from the heart to the organs and serve as a pressure reservoir to continue driving blood forward when the heart is relaxing and filling. The mean arterial blood pressure is closely regulated to ensure adequate blood delivery to

the organs. The amount of blood that flows through a given organ depends on the calibre (internal diameter) of the highly muscular arterioles that supply the organ. Arteriolar calibre is subject to control so that cardiac output can be constantly readjusted to best serve the body's needs at each moment. The thin-walled, pore-lined capillaries are the actual site of exchange between blood and the surrounding tissue cells. The highly distensible veins return blood from the organs to the heart and also serve as a blood reservoir.

Clinical Connections

John is 63 years old and recently retired. He was diagnosed with hypertension at age 40, but his blood pressure has been well maintained. He has been a pack-a-day smoker since the age of 15. His weight has always been on the heavy side, and his family physician has recommended he lose weight. He tries to walk regularly, but finds that after he walks a short distance, he starts to feel pain and sometimes cramps in his right calf. When this happens he stops and the symptoms quickly go away. He can then walk again, but the symptoms return. Some days are better than others, and he has developed a walk-rest pattern for his daily exercise. When his physician next asks how his exercise is going, John describes what has been happening.

Upon recognizing the symptoms, his physician conducted an ankle-brachial index, which involves comparing the systolic blood pressure measured in the right ankle to blood pressure measured in the right arm. John's ankle-brachial index was found to be 0.85. Subsequently, an ultrasound revealed significant blockage in an artery, and John was diagnosed with intermittent claudication, a symptom of peripheral artery disease. John underwent angioplasty, quit smoking, and is now able to exercise without any problem.

9.1 | Introduction

Most body cells are not in direct contact with the external environment, yet these cells must make exchanges with this environment, such as picking up oxygen and nutrients and eliminating wastes. Furthermore, chemical messengers must be transported between cells to accomplish integrated activity. To achieve these long-distance exchanges, cells are linked with one another and with the external environment by vascular (blood vessel) highways. Blood is transported to all parts of the body through a system of vessels that brings fresh supplies to the vicinity of all cells while removing their wastes.

To review cardiac circulation, all blood pumped by the right side of the heart passes through the pulmonary circulation to the lungs for oxygen pickup and carbon dioxide removal. The blood pumped by the left side of the heart (ventricle) enters the systemic circulation for distribution to the systemic organs. This delivery of oxygenated blood occurs through a parallel arrangement of vessels that branch from the aorta (► Figure 9-1), which ensures that all organs receive blood of the same composition (O_2 , CO_2). Because of this parallel arrangement, blood flow through each systemic organ can be independently adjusted as needed.

In this chapter, we first examine some general principles regarding blood flow patterns and the physics of blood flow. Then we turn our attention to the roles of the various types of blood vessels through which blood flows. We end the chapter by discussing how blood pressure is regulated to ensure adequate delivery of blood to the tissues.

Maintenance of homeostasis

Metabolically active cells of the body are constantly exchanging oxygen and nutrients for carbon dioxide and waste products. As a result, blood constantly needs to be reconditioned so that its composition remains relatively stable, despite an ongoing drain of supplies to support metabolic activities and despite the continual addition of wastes from the tissues. Organs that recondition the blood (e.g., the kidneys) normally receive much more blood than necessary to meet their basic metabolic needs; the extra blood is used to perform their physiological role in maintaining homeostasis. For example, large percentages of the cardiac output are distributed to the digestive tract (to pick up nutrient supplies), to the kidneys (to eliminate metabolic wastes and adjust water and electrolyte composition), and to the skin (to eliminate heat). Blood flow to the other organs—heart, skeletal muscles, and so on—is solely for filling these organs' metabolic needs, and this flow can be adjusted according to the level of activity in these organs. For example, during exercise, additional blood is delivered to the active muscles to meet their increased metabolic needs.

Because the reconditioning organs—digestive organs, kidneys, and skin—receive more blood flow than they need for their own functioning, they can withstand temporary reductions in blood flow much better than can other organs that do not have this extra margin of blood supply. The brain in particular suffers irreparable damage when transiently deprived of blood supply. After only four minutes without oxygen, permanent

► **FIGURE 9-1 Distribution of cardiac output at rest.** The lungs receive all the blood pumped out by the right side of the heart, whereas the systemic organs each receive some of the blood pumped out by the left side of the heart. The percentage of pumped blood received by the various organs under resting conditions is indicated. This distribution of cardiac output can be adjusted as needed.

brain damage may occur. Therefore, a high priority in the overall operation of the circulatory system is the constant delivery of adequate blood to the brain, which can least tolerate disrupted blood supply.

In Section 8.3, you will see how the distribution of cardiac output is adjusted according to the body's immediate needs. For now, we are going to concentrate on the factors that influence blood flow through a given blood vessel.

Blood flow and the pressure gradient

The **flow rate** of blood through a vessel (i.e., the volume of blood passing through per unit of time) is directly proportional

to the pressure gradient and inversely proportional to vascular resistance:

$$F = \frac{\Delta P}{R}$$

where

F = flow rate of blood through a vessel

ΔP = pressure gradient

R = resistance of blood vessels

PRESSURE GRADIENT

The **pressure gradient** is the difference in pressure between the beginning and end of a vessel. Blood flows from an area of higher pressure to an area of lower pressure down a pressure gradient. Contraction of the heart imparts pressure to the blood, which is the main driving force for flow through a vessel. Because of frictional losses (resistance), the pressure drops as blood flows throughout the vessel's length. Accordingly, pressure is higher at the beginning than at the end of the vessel, and this difference establishes a pressure gradient for forward flow of blood through the vessel. The greater the pressure gradient forcing blood through a vessel, the greater the flow rate through that vessel (► Figure 9-2a). Think of a garden hose attached to a faucet. If you turn on the faucet slightly, a small stream of water flows out of the end of the hose, because the pressure is slightly greater at the beginning than at the end of the hose. If you open the faucet all the way, the pressure gradient increases tremendously, so that water flows through the hose much faster and spurts from the end of the hose. Note that the *difference* in pressure between the two ends of a vessel, not the absolute pressures within the vessel, determines flow rate (► Figure 9-2b).

RESISTANCE

The other factor influencing flow rate through a vessel is **resistance**, which is a measure of the hindrance or opposition to blood flow through a vessel, caused by friction between the moving fluid and the stationary vascular walls. As resistance to flow increases, it is more difficult for blood to pass through the vessel, so flow rate decreases (as long as the pressure gradient remains unchanged). When resistance increases, the pressure gradient must increase correspondingly to maintain the same flow rate. Accordingly, when the vessels offer more resistance to flow, the heart must work harder to maintain adequate circulation.

Resistance to blood flow depends on three factors: (1) viscosity of the blood, (2) vessel length, and (3) vessel radius. The last of these three is by far the most important. The term **viscosity** (designated as η) refers to the friction developed between the molecules of a fluid as they slide over each other during flow of the fluid. The greater the viscosity is, the greater the resistance to flow. In general, the thicker a liquid, the more viscous it is. For example, molasses flows more slowly than water, because molasses has greater viscosity. Blood viscosity is determined primarily by the number of circulating red blood cells. Normally, this factor is relatively constant and thus not important in controlling resistance. Occasionally, however, blood viscosity and, accordingly, resistance to flow, are altered by an abnormal

$$\text{Flow} \propto \Delta P$$

(a)

$$\text{Flow} \propto \Delta P$$

► **FIGURE 9-2 Relationship of flow to the pressure gradient in a vessel.**

(a) As the difference in pressure (P) between the two ends of a vessel increases, the flow rate increases proportionally. (b) Flow rate is determined by the *difference* in pressure between the two ends of a vessel, not the magnitude of the pressures at each end.

number of red blood cells. When excessive red blood cells are present, blood flow is more sluggish than normal.

Because blood “rubs” against the lining of the vessels as it flows past, the greater the vessel surface area in contact with the blood, the greater the resistance to flow. Surface area is determined by both the length (L) and the radius (r) of the vessel. At a constant radius, the longer the vessel is, the greater the surface area and the greater the resistance to flow. Because vessel length remains constant in the body, it is not a variable factor in the control of vascular resistance.

Therefore, the major determinant of resistance to flow is the vessel's radius. Fluid passes more readily through a large vessel than through a smaller vessel. This occurs because a given volume of blood comes in contact with much more of the surface area in a small-radius vessel than it does in a large-radius vessel, and this increased contact results in greater resistance (► Figure 9-3a).

(a)

Radius in vessel 2 = 2 times that of vessel 1

Resistance in vessel 2 = 1/16 that of vessel 1

Flow in vessel 2 = 16 times that of vessel 1

$$\text{Resistance} \propto 1/r^4$$

$$\text{Flow} \propto r^4$$

(b)

© 2016 Cengage

FIGURE 9-3 Relationship of resistance and flow to the vessel radius.

(a) The same volume of blood comes into contact with a greater surface area of a small-radius vessel compared with a large-radius vessel. Accordingly, the small-radius vessel offers more resistance to blood flow, because the blood “rubs” against a larger surface area. (b) Doubling the radius decreases the resistance to 1/16 and increases the flow 16 times, because the resistance is inversely proportional to the fourth power of the radius.

Furthermore, a slight change in the radius of a vessel brings about a notable change in flow, because the resistance is inversely proportional to the fourth power of the radius (multiplying the radius by itself four times):

$$R \propto \frac{1}{r^4}$$

Doubling the radius therefore reduces the resistance to 1/16th its original value ($r^4 = 2 \times 2 \times 2 \times 2 = 16$; $R \propto 1/16$) and brings about a sixteenfold increase in flow through the vessel (at the same pressure gradient) (Figure 9-3b). The converse is also true. Only 1/16th as much blood flows through a vessel at the same driving pressure as when its radius is halved. Importantly, the radius of arterioles can be regulated; this is the most important factor in controlling resistance to blood flow throughout the vascular circuit.

POISEUILLE’S LAW

The factors that affect the flow rate through a vessel are integrated in **Poiseuille’s law**, as follows:

$$\text{Flow rate} = \frac{\pi \Delta P r^4}{8 \eta L}$$

The significance of the relationships among flow, pressure, and resistance—as largely determined by vessel radius—will become more apparent as we embark on a voyage through the vessels in the next section, The Vascular Tree.

Clinical Connections

John has peripheral artery disease due to atherosclerosis (see Chapter 8, p. 372).

Tissue blood flow remains relatively constant unless there is an increase in pressure. At rest, pressure is relatively constant, and a partial arterial blockage caused by atherosclerosis causes an increase in resistance, which means there is decreased blood flow at rest. During exercise, the plaque restricts dilation of the artery, so blood flow is further compromised. The consequences of this decreased flow during exercise are discussed later.

The vascular tree

The systemic and pulmonary circulations each consist of a closed system of vessels (Figure 9-4). (For the history leading up to the conclusion that blood vessels form a closed system, see Concepts, Challenges, and Controversies.) These vascular loops each consist of a continuum of different blood vessel types that begins and ends with the heart. Here, we examine this system of vessels by looking specifically at the systemic circulation. Arteries, which carry blood from the heart to the organs, branch, or diverge, into a tree of progressively smaller vessels, with the various branches delivering blood to different regions of the body. When a small artery reaches the organ it supplies, it branches into numerous arterioles. The volume of blood flowing through an organ can be adjusted by regulating the internal diameter of the organ’s arterioles. Arterioles branch further within the organs into capillaries, the smallest vessels, across which all exchanges are made with surrounding cells. Capillary exchange is the entire purpose of the **circulatory system**; all other activities of the system are directed toward ensuring an adequate distribution of replenished blood to capillaries for exchange with all cells. Capillaries rejoin to form small **venules**, which further merge to form small **veins** that leave the organs. The small veins progressively unite or converge to form larger veins that eventually empty into the heart. The arterioles, capillaries, and venules are collectively referred to as the **microcirculation**, because they are only visible through a microscope. The microcirculatory vessels are all located within the organs. The pulmonary circulation consists of the same vessel types, except that all the blood in this loop goes between the heart and lungs. If all of the vessels in the body were strung end to end, they could circle the circumference of Earth twice!

The structure of blood vessels

Before learning about the major types of blood vessels in the body, you need to have an understanding of blood vessel structure, which is important for understanding blood vessel function.

► **FIGURE 9-4 Basic organization of the cardiovascular system.** Arteries progressively branch as they carry blood from the heart to the organs. A separate small arterial branch delivers blood to each of the various organs. As a small artery enters the organ it is supplying, it branches into arterioles, which further branch into an extensive network of capillaries. The capillaries rejoin to form venules, which further unite to form small veins that leave the organ. The small veins progressively merge as they carry blood back into the heart.

Blood vessel walls are made up of alternating layers of connective tissue (both fibrous and elastic), smooth muscle cells, and epithelial cells. The outermost layer is called the *tunica adventitia* and mainly consists of collagen-rich connective tissue. The middle layer, the *tunica media*, is the thickest and contains circular arrangements of connective tissue and smooth muscle cells. In some vessels, an elastic fibre-rich area called the **external elastic lamina** may be found between the *tunica adventitia* and the *tunica media*. The innermost layer is the *tunica intima* and consists of a single layer of endothelial cells (the endothelium) surrounded by a basement membrane of connective tissues and, in some vessels, an additional layer of elastic fibres called the **internal elastic lamina**.

Each of these layers serves distinct physiological roles depending on the function of the blood vessel. Consequently, the relative thicknesses and even the presence of these layers vary dramatically throughout the vascular tree. ■ Table 9-1 summarizes the features of the blood vessel types, which are further discussed in Sections 9.2 through 9.4.

Check Your Understanding 9.1

1. Describe the distribution of blood flow at rest, and postulate how this might change during exercise.
2. Name the reconditioning organs.
3. Give the equation showing the relationship among flow rate of blood through a vessel, the pressure gradient, and the resistance to flow, and give the equation for the relationship between resistance and vessel radius.

9.2 Arteries

Rapid-transit passageways and pressure reservoirs

Arteries are specialized to (1) serve as rapid-transit passageways for blood from the heart to the organs (because of their large radius, arteries offer little resistance to blood flow), and (2) act as a **pressure reservoir** to provide the driving force for blood when the heart is relaxing.

We discussed the first point in the section on blood vessels and pressure gradient. Here we expand on the arteries' second specialization, as pressure reservoir. The heart alternately contracts to pump blood into the arteries and then relaxes to refill with blood from the veins. When the heart is relaxing and refilling, no blood is pumped out. However, capillary flow does not fluctuate between cardiac systole and diastole; that is, blood flow is continuous through the capillaries supplying the organs. The driving force for the continued flow of blood to the organs during cardiac relaxation is provided by the elastic properties of the arterial walls.

All vessels are lined with a thin layer of smooth, flat, endothelial cells that are continuous with the endothelial lining (the endocardium) of the heart. A thick wall made up of smooth muscle and connective tissue surrounds the arteries' endothelial lining. Arterial connective tissue contains an abundance of two types of connective tissue fibres: *collagen fibres*, which provide tensile strength against the high driving pressure of blood ejected from the heart; and *elastin fibres*, which give the arterial walls elasticity so that they behave much like a balloon (► Figure 9-5).

As the heart pumps blood into the arteries during ventricular systole, a greater volume of blood enters the arteries from the heart than leaves them to flow into smaller vessels downstream, because the smaller vessels have a greater resistance to flow. The arteries' elasticity enables them to expand to temporarily hold this excess volume of ejected blood, so they store some of the pressure energy imparted by cardiac contraction in their stretched walls—just as a balloon expands to accommodate the extra volume of air you blow into it (► Figure 9-6a). When the heart relaxes and ceases pumping blood into the arteries, the stretched arterial walls passively recoil, like an inflated balloon that is released. This recoil pushes the excess blood contained in the arteries into the vessels downstream, ensuring continued blood flow to the organs when the heart is relaxing (► Figure 9-6b).

From Humours to Harvey: Historical Highlights in Circulation

TODAY, EVEN GRADE-SCHOOL CHILDREN KNOW that blood is pumped by the heart and continually circulates throughout the body in a system of blood vessels. Furthermore, people accept without question that blood picks up oxygen in the lungs from the air we breathe and delivers it to the various organs. This common knowledge was unknown for most of human history, however. Even though the function of blood was described as early as the 5th century BC, our modern concept of circulation did not develop until 1628, more than 2000 years later, when William Harvey published his now classical study on the circulatory system.

Ancient Greeks believed everything material in the universe consisted of just four elements: earth, air, fire, and water. Extending this view to the human body, they thought these four elements took the form of four “humours”: *black bile* (representing earth), *blood* (representing air), *yellow bile* (representing fire), and *phlegm* (representing water). According to the Greeks, disease resulted when one humour was out of normal balance with the rest. The “cure” was logical: to restore normal balance, drain off whichever humour was in excess. Because the easiest humour to drain off was the blood, bloodletting became standard procedure for treating many illnesses—a practice that persisted well into the Renaissance (which began in the 1300s and extended into the 1600s).

Although the ancient Greeks’ notion of the four humours was erroneous, their concept of the necessity of balance within the body was remarkably accurate. As we now know, life depends on homeostasis, maintenance of the proper balance among all elements of the internal environment.

Aristotle (384–322 BC), a biologist as well as a philosopher, was among the first to correctly describe the heart as the centre of a system of blood vessels. However, he thought the heart was both the seat of intellect (the brain was not identified as the seat of intellect until more than a century later) and a furnace that heated the blood. He considered this warmth the vital force of life, because the body cools quickly at death. Aristotle also erroneously theorized that breathing ventilated the “furnace,” with air serving as a cooling agent. Aristotle could observe with his eyes the arteries and veins in cadavers but did not have a microscope with which to observe capillaries. (The microscope was not invented until the 17th century.) Thus, he did not think arteries and veins were directly connected.

In the 3rd century BC, Erasistratus, a Greek many considered the first physiologist, proposed that the liver used food to make blood, which the veins delivered to the other organs. He believed the arteries contained air, not blood. According to his view, *pneuma* (air), a living force, was taken in by the lungs, which transferred it to the heart. The heart transformed the air into a “vital spirit” that the arteries carried to the other organs.

Galen (AD 130–206), a prolific, outspoken, dogmatic Roman physician, philosopher, and scholar, expanded on the work of Erasistratus and others who had preceded him. Galen further elaborated on the pneumatic theory. He proposed three fundamental members in the body, from lowest to highest: liver, heart, and brain. Each was dominated by a

special *pneuma*, or spirit. (In Greek, *pneuma* encompassed the related ideas of air, breath, and spirit.) Like Erasistratus, Galen believed that the liver made blood from food, taking on a “natural spirit” (*pneuma physicon*) in the process. The newly formed blood then proceeded through veins to organs. The natural spirit, which Galen considered a vapour rising from the blood, controlled the functions of nutrition, growth, and reproduction. Once its spirit supply was depleted, the blood moved in the opposite direction through the same venous pathways, returning to the liver to be replenished. When the natural spirit was carried in the venous blood to the heart, it mixed with air that was breathed in and transferred from the lungs to the heart. Contact with air in the heart transformed the natural spirit into a higher-level spirit, the “vital spirit” (*pneuma zotikon*). The vital spirit, which was carried by the arteries, conveyed heat and life throughout the body. The vital spirit was transformed further into a yet higher animal, or psychical, spirit (*pneuma psychikon*) in the brain. This ultimate spirit regulated the brain, nerves, feelings, and so on. Thus, according to Galenic theory, the veins and arteries were conduits for carrying different levels of *pneuma*, and there was no direct connection between the veins and arteries. The heart was not involved in moving blood but instead was the site where blood and air mixed. (We now know that blood and air meet in the lungs for the exchange of oxygen and carbon dioxide.)

Galen was one of the first to understand the need for experimentation, but unfortunately, his impatience and his craving for philosophical and literary fame led him to expound comprehensive theories that were not always based on the time-consuming collection of evidence. Even though his assumptions about bodily structure and functions often were incorrect, his theories were convincing because they seemed a logical way of pulling together what was known at the time. Furthermore, the sheer quantity of his writings helped establish him as an authority. In fact, his writings remained the anatomic and physiological “truth” for nearly 15 centuries, throughout the Middle Ages and well into the Renaissance. So firmly entrenched was Galenic doctrine that people who challenged its accuracy risked their lives by being declared secular heretics.

Not until the Renaissance and the revival of classical learning did independent-minded European investigators begin to challenge Galen’s theories. Most notably, the English physician William Harvey (1578–1657) revolutionized the view of the roles played by the heart, blood vessels, and blood. Through careful observations, experimentation, and deductive reasoning, Harvey was the first to correctly identify the heart as a pump that repeatedly moves a small volume of blood forward in one fixed direction in a circular path through a closed system of blood vessels (the *circulatory system*). He also correctly proposed that blood travels to the lungs to mix with air (instead of air travelling to the heart to mix with blood). Even though he could not see physical connections between arteries and veins, he speculated on their existence. Not until the discovery of the microscope later in the century was the existence of these connections—capillaries—confirmed by Marcello Malpighi (1628–1694).

■ **TABLE 9-1** Features of Blood Vessels

VESSEL TYPE																													
FEATURE	Arteries	Arterioles	Capillaries	Veins																									
Number	Several hundred*	Half a million	Ten billion	Several hundred*

Arterial pressure and diastole

Blood pressure, the force exerted by the blood against a vessel wall, depends on the volume of blood contained within the vessel and the **compliance**, or **distensibility**, of the vessel walls (how easily they can be stretched). If the volume of blood entering the arteries were equal to the volume of blood leaving the arteries during the same period, arterial blood pressure would remain constant. This is not the case, however. During ventricular systole, a stroke volume of blood enters the arteries from the

ventricle, but only about one-third as much blood leaves the arteries to enter the arterioles. During diastole, no blood enters the arteries, although blood continues to leave them, driven by elastic recoil. The maximum pressure exerted in the arteries when blood is ejected into them during systole, the **systolic pressure**, averages 120 mmHg. The minimum pressure within the arteries when blood is draining off into the rest of the vessels during diastole, the **diastolic pressure**, averages 80 mmHg (► Figure 9-7; see also ► Figure 8-16).

► **FIGURE 9-5 Elastin fibres in an artery.** Light micrograph of a portion of the aorta wall in cross-section, showing the numerous wavy elastin fibres common to all arteries.

Blood pressure can be measured using a sphygmomanometer

The changes in arterial pressure throughout the cardiac cycle can be measured directly by connecting a pressure-measuring device to a needle inserted in an artery. However, it is more convenient and reasonably accurate to measure the pressure indirectly with a **sphygmomanometer**: an externally applied inflatable

► **FIGURE 9-7 Arterial blood pressure.** The systolic pressure is the peak pressure exerted in the arteries when blood is pumped into them during ventricular systole. The diastolic pressure is the lowest pressure exerted in the arteries when blood is draining off into the vessels downstream during ventricular diastole. The pulse pressure is the difference between systolic and diastolic pressure. The mean pressure is the average pressure throughout the cardiac cycle.

cuff attached to a pressure gauge. When the cuff is wrapped around the upper arm and then inflated with air, the pressure of the cuff is transmitted through the tissues to the underlying brachial artery, the main vessel carrying blood to the forearm (► Figure 9-8). The technique involves balancing the pressure in the cuff against the pressure in the artery. When cuff pressure is greater than the pressure in the vessel, the vessel is pinched closed so that no blood flows through it. When blood pressure is greater than cuff pressure, the vessel is open and blood flows through.

DETERMINATION OF SYSTOLIC AND DIASTOLIC PRESSURE

During a test to determine blood pressure, a stethoscope is placed over the brachial artery at the inside bend of the elbow just below the cuff. No sound can be detected either when blood is not flowing through the vessel or when blood is flowing in the normal, smooth laminar flow (p. 364). Turbulent blood flow, in contrast, creates vibrations that can be heard. The sounds heard when determining blood pressure, known as **Korotkoff sounds**, are distinct from the heart sounds associated with valve closure heard when listening to the heart with a stethoscope.

At the onset of a blood pressure determination, the cuff is inflated to a pressure greater than systolic blood pressure so that the brachial artery collapses. Because the externally applied pressure is greater than the peak internal pressure, the artery remains completely pinched closed throughout the entire cardiac cycle; no sound can be heard, because no blood is passing through (point 1 in ► Figure 9-8b). As air in the cuff is slowly released, the pressure in the cuff is gradually reduced. When the cuff pressure falls to just below the peak systolic pressure, the artery transiently opens a bit when the

► **FIGURE 9-6 Arteries as a pressure reservoir.** Because of their elasticity, arteries act as a pressure reservoir. (a) The elastic arteries distend during cardiac systole as more blood is ejected into them than drains off into the narrow, high-resistance arterioles downstream. (b) The elastic recoil of arteries during cardiac diastole continues driving the blood forward when the heart is not pumping.

► **FIGURE 9-8 Sphygmomanometry.** (a) Use of a sphygmomanometer in determining blood pressure. The pressure in the inflatable cuff can be varied to prevent or permit blood flow in the underlying brachial artery. Turbulent blood flow can be detected with a stethoscope, whereas smooth laminar flow and no flow are inaudible. (b) Patterns of sounds in relation to cuff pressure compared with blood pressure. (c) Blood flow through the brachial artery in relation to cuff pressure and sounds

blood pressure reaches this peak. Blood escapes through the partially occluded artery for a brief interval before the arterial pressure falls below the cuff pressure and the artery collapses once again. This spurt of blood is turbulent, so it can be heard. So the highest cuff pressure at which the *first sound* can be heard indicates the *systolic pressure* (point **2**). As the cuff pressure continues to fall, blood intermittently spurts through the artery and produces a sound with each subsequent cardiac cycle whenever the arterial pressure exceeds the cuff pressure (point **3**).

When the cuff pressure finally falls below diastolic pressure, the brachial artery is no longer pinched closed during any part of the cardiac cycle, and blood can flow uninterrupted through the vessel (point **5**). With the return of non-turbulent blood

flow, no further sounds can be heard. Therefore, the highest cuff pressure at which the *last sound* can be detected indicates the *diastolic pressure* (point **4**).

In clinical practice, arterial blood pressure is expressed as systolic pressure over diastolic pressure, with the cut-off for desirable blood pressure being less than 120/80 (120 over 80) mmHg.

PULSE PRESSURE

The pulse that can be felt in an artery lying close to the surface of the skin is due to the difference between systolic and diastolic pressures. This pressure difference is known as the **pulse pressure**. When blood pressure is 120/80, pulse pressure is 40 mmHg (120 – 80 mmHg).

Mean arterial pressure

The **mean arterial pressure** is the *average pressure* driving blood forward into the tissues throughout the cardiac cycle. Contrary to what you might expect, mean arterial pressure is not the halfway value between systolic and diastolic pressure (e.g., with a blood pressure of 120/80, mean pressure is not 100 mmHg). The reason is that arterial pressure remains closer to diastolic than to systolic pressure for a longer portion of each cardiac cycle. At resting heart rate, about two-thirds of the cardiac cycle is spent in diastole, and only one-third in systole. As an analogy, if a race car travelled 80 km per hour (km/h) for 40 minutes and 120 km/h for 20 minutes, its average speed would be 93 km/h, not the halfway value of 100 km/h.

Similarly, a good approximation of the mean arterial pressure can be determined using the following formula:

Mean arterial pressure = diastolic pressure + $1/3$ pulse pressure

At 120/80, mean arterial pressure = 80 mmHg + $(1/3)$ 40 mmHg
= 93 mmHg

The mean arterial pressure, not the systolic or diastolic pressure, is monitored and regulated by blood pressure reflexes (described in Section 8.6).

Because arteries offer little resistance to flow, only a negligible amount of pressure energy is lost in them due to friction. Therefore, arterial pressure—systolic, diastolic, pulse, or mean—is essentially the same throughout the arterial tree (► Figure 9-9).

Blood pressure exists throughout the entire vascular tree. However, when discussing a person's blood pressure without qualifying which blood vessel type is referred to, the term is tacitly understood to mean the pressure in the arteries.

Check Your Understanding 9.2

1. Compare and contrast the composition of the walls for large arteries and large veins.
2. Indicate what structural feature enables arteries to serve as a pressure reservoir.
3. Draw a graph of average arterial blood pressure throughout the cardiac cycle, labelling the systolic pressure, diastolic pressure, and pulse pressure.

9.3 | Arterioles

When an artery reaches the organ it is supplying, it branches into numerous arterioles within the organ.

The major resistance vessels

Arterioles are the major resistance vessels in the vascular tree because their radius is small enough to offer considerable resistance to flow. (Even though capillaries have a smaller radius than arterioles, collectively they do not offer as much resistance to flow

as the arterioles do.) In contrast to the low resistance of the arteries, the high degree of arteriolar resistance causes a marked drop in mean pressure as blood flows through these small vessels. On average, the pressure falls from 93 mmHg, the mean arterial pressure (the pressure of the blood entering the arterioles), to 37 mmHg, the pressure of the blood leaving the arterioles and entering the capillaries (► Figure 9-9). This decline in pressure helps establish the pressure differential that encourages the flow of blood from the heart to the various organs downstream. If no pressure drop occurred in the arterioles, the pressure at the end of the arterioles (i.e., at the beginning of the capillaries) would be equal to the mean arterial pressure. No pressure gradient would exist to drive blood from the heart to the tissue capillary beds.

Arteriolar resistance also converts the pulsatile systolic-to-diastolic pressure swings in the arteries into the nonpulsatile pressure present in the capillaries. The non-fluctuating pressure that the arterioles create is a key component in mean arterial pressure (p. 419). Another variable in the determination of mean arterial pressure is total peripheral resistance, which again is influenced by arteriolar resistance. This illustrates the influence of arteriolar resistance in determining the overall pressure in our vascular system.

► **FIGURE 9-9** Pressures through the systemic circulation. Left ventricular pressure swings between a low pressure of 0 mmHg during diastole to a high pressure of 120 mmHg during systole. Arterial blood pressure, which fluctuates between a peak systolic pressure of 120 mmHg and a low diastolic pressure of 80 mmHg each cardiac cycle, is of the same magnitude throughout the large arteries. Because of the arterioles' high resistance, the pressure drops precipitously, and the systolic-to-diastolic swings in pressure are converted to a nonpulsatile pressure when blood flows through the arterioles. The pressure continues to decline, but at a slower rate, as blood flows through the capillaries and venous system.

(d) Outcome of and factors causing arteriolar vasodilation

The radius (and, accordingly, the resistances) of arterioles supplying individual organs can be adjusted independently to accomplish two functions: (1) to variably distribute the cardiac output among the systemic organs, depending on the body's momentary needs; and (2) to help regulate arterial blood pressure. Before considering how such adjustments are important in accomplishing these two functions, we will discuss the mechanisms involved in adjusting arteriolar resistance.

VASOCONSTRICTION AND VASODILATION

Unlike arteries, arteriolar walls contain very little elastic connective tissue. However, they do have a thick layer of smooth muscle that is richly innervated by sympathetic nerve fibres. The smooth muscle is also sensitive to many local chemical changes and to a few circulating hormones. The smooth muscle layer runs circularly around the arteriole (▶ Figure 9-10a), so when the smooth muscle layer contracts, the vessel's circumference (and its radius) becomes smaller, which increases resistance and decreases flow through that vessel. **Vasoconstriction** is the term applied to such narrowing of a vessel (▶ Figure 9-10c). The term **vasodilation** refers to enlargement in the circumference and radius of a vessel as a result of its smooth muscle layer relaxing (▶ Figure 9-10d). Vasodilation leads to decreased resistance and increased flow through that vessel.

VASCULAR TONE

Arteriolar smooth muscle normally displays a state of partial constriction known as **vascular tone**, which establishes a baseline of arteriolar resistance (▶ Figure 8-10b). Two factors are responsible for vascular tone. First, arteriolar smooth muscle has considerable myogenic activity; that is, its membrane potential fluctuates independent of any neural or hormonal influences, leading to self-induced contractile activity (p. 332). Second, the sympathetic fibres supplying most arterioles continually release norepinephrine, which further enhances vascular tone.

This ongoing tonic activity makes it possible to either increase or decrease the level of contractile activity to accomplish vasoconstriction or vasodilation, respectively. Were it not for tone, it would be impossible to reduce the tension in an arteriolar wall to accomplish vasodilation; only varying degrees of vasoconstriction would be possible.

A variety of factors can influence the level of contractile activity in arteriolar smooth muscle, thereby substantially

changing resistance to flow in these vessels. These factors fall into two categories: local (intrinsic) controls, which are important in determining the distribution of cardiac output; and extrinsic controls, which are important in blood pressure regulation. Now we begin our discussion of local controls; the discussion of extrinsic control begins in the section Extrinsic Sympathetic Control of Arteriolar Radius.

Arteriolar radius

Local (intrinsic) controls are changes within an organ that alter the radius of the vessels and hence adjust blood flow through the organ by directly affecting the smooth muscle of the organ's arterioles. Local influences may be either chemical or physical. Local chemical influences on arteriolar radius include (1) local metabolic changes and (2) histamine release. Local physical influences include (1) local application of heat or cold, (2) chemical response to shear stress, and (3) myogenic response to stretch. These local influences, chemical and physical, play essential roles in regulating arteriolar radius.

The fraction of the total cardiac output delivered to each organ is not always constant: it varies, depending on the demands for blood at the time. The amount of the cardiac output received by each organ is determined by the number and calibre of the arterioles supplying that area. Recall that $F = \Delta P/R$. Because blood is delivered to all organs at the same mean arterial pressure, the driving force for flow is identical for each organ. Therefore, differences in flow to various organs are completely determined by differences in the extent of vascularization and by differences in resistance offered by the arterioles supplying each organ. On a moment-to-moment basis, the distribution of cardiac output can be varied by differentially adjusting arteriolar resistance in the various vascular beds.

As an analogy, consider a water pipe that has a number of adjustable valves located throughout its length (► Figure 9-11). Assuming that water pressure in the pipe is constant, differences in the amount of water flowing into a beaker under each valve depend entirely on which valves are open and to what extent. No water enters beakers under closed valves (high resistance), and more water flows into beakers under valves that are opened completely (low resistance) than into beakers under valves that are only partially opened (moderate resistance).

Similarly, more blood flows to areas whose arterioles offer the least resistance to its passage. During exercise, for example,

► FIGURE 9-11 Flow rate as a function of resistance

© 2016 Cengage

not only is cardiac output increased, but, because of vasodilation in skeletal muscle and in the heart, a greater percentage of the pumped blood is diverted to these organs to support their increased metabolic activity. Simultaneously, blood flow to the digestive tract and kidneys is reduced as a result of arteriolar vasoconstriction in these organs (► Figure 9-12). Only the blood supply to the brain remains remarkably constant no matter what a person is doing, be it vigorous physical activity, intense mental concentration, or sleep. Although total blood flow to the brain remains constant, imaging (MRI) and noninvasive measurement (Doppler) techniques demonstrate that regional blood flow varies within the brain in close correlation with local neural activity patterns.

We now examine the role and mechanism of the local influences on arteriolar radius.

Local influences on arteriolar radius

The most important local chemical influences on arteriolar smooth muscle are related to metabolic changes within a given organ. The influence of these local changes on arteriolar radius is important in matching blood flow through an organ with the organ's metabolic needs, ultimately with the intent of maintaining homeostasis within that tissue and the whole body. Local metabolic controls are especially important in skeletal muscle and the heart—organs whose metabolic activity and need for blood supply normally vary most extensively. Local metabolic controls are also important in the brain, whose overall metabolic activity and need for blood supply remain constant. Local controls help maintain the constancy of blood flow to the brain.

FIGURE 9-12 Magnitude and distribution of the cardiac output at rest and during moderate exercise. Not only does cardiac output increase during exercise, but the distribution of cardiac output is also adjusted to support the heightened physical activity. The percentage of cardiac output going to the skeletal muscles and heart rises, thereby delivering extra oxygen and nutrients needed to support these muscles' stepped-up rate of ATP consumption. The percentage going to the skin increases as a way to eliminate from the body surface the extra heat generated by the exercising muscles. The percentage going to most other organs shrinks. Only the magnitude of blood flow to the brain remains unchanged while the distribution of cardiac output is readjusted during exercise.

ACTIVE HYPERAEMIA

Arterioles lie within the organ they are supplying and can be acted on by local factors within that organ. During increased metabolic activity, such as when a skeletal muscle is contracting during exercise, local concentrations of a number of the organ's

chemicals change. For example, the local oxygen concentration decreases as the actively metabolizing cells use up more oxygen to support oxidative phosphorylation for ATP production. This and other local chemical changes produce local arteriolar dilation by triggering relaxation of the arteriolar smooth muscle in

the vicinity. Local arteriolar vasodilation then increases blood flow to that particular area, a response called **active hyperaemia** (*hyper* means “above normal”; *aemia* means “blood”). When cells are more metabolically active, they require more blood to bring in oxygen and nutrients and to remove metabolic wastes. The increased blood flow meets these increased local needs.

Conversely, when an organ, such as a relaxed muscle, is less metabolically active and thus has reduced needs for blood delivery, the resultant local chemical changes (e.g., increased local oxygen concentration) bring about local arteriolar vasoconstriction and a subsequent reduction in blood flow to the area. Local metabolic changes can thus adjust blood flow as needed without involving nerves or hormones.

LOCAL METABOLIC CHANGES THAT INFLUENCE ARTERIOLAR RADIUS

A variety of local chemical changes act together in a cooperative, redundant manner to bring about these “selfish” local adjustments in arteriolar calibre that match a tissue’s blood flow with its needs. Specifically, the following local chemical factors produce relaxation of arteriolar smooth muscle (vasodilation):

- *Decreased oxygen*, a result of increased oxidative metabolism and thus oxygen uptake by cells.
- *Increased carbon dioxide*, a by-product of increased oxidative phosphorylation.
- *Increased acid*. More carbonic acid is generated from the increased carbon dioxide production. Also, lactic acid accumulates if the glycolytic pathway is used for ATP production.
- *Increased potassium*. In actively contracting muscles, repeated action potentials outpace the ability of the $\text{Na}^+ - \text{K}^+$ pump to restore the resting concentration gradients and result in an increase in K^+ in the tissue fluid.
- *Increased osmolarity*. Osmolarity (the concentration of osmotically active solutes/particles) increases during elevated cellular metabolism because of increased formation of osmotically active particles.
- *Adenosine release*. Especially in cardiac muscle, adenosine is released in response to increased metabolic activity or oxygen deprivation.
- *Prostaglandin release*. Prostaglandins are local chemical messengers derived from fatty acid chains within the plasma membrane.

The relative contributions of the aforementioned chemicals (and possibly others) in the local metabolic control of arteriole blood flow are currently being investigated.

LOCAL VASOACTIVE MEDIATORS

These local chemical changes do not act directly on vascular smooth muscle to change its contractile state. Instead, **endothelial cells**, the single layer of specialized epithelial cells that line the lumen of all blood vessels, release chemical mediators

that play a key role in locally regulating arteriolar calibre. Until recently, scientists regarded endothelial cells as little more than a passive barrier between the blood and the rest of the vessel wall. It is now known that endothelial cells are active participants in a variety of vessel-related activities, some of which are described in ■ Table 9-2. Among these functions, endothelial cells release locally acting chemical messengers in response to chemical changes in their environment (such as a reduction in oxygen) or physical changes (such as stretching of the vessel wall). These local vasoactive (acting on vessels) mediators act on the underlying smooth muscle to alter its state of contraction.

Among the best studied of these local vasoactive mediators is **nitric oxide (NO)**, which causes local arteriolar vasodilation by inducing relaxation of arteriolar smooth muscle in the vicinity. It does so by inhibiting the entry of contraction-inducing calcium into these smooth muscle cells. Nitric oxide is a small, highly reactive, short-lived gas molecule that once was known primarily as a toxic air pollutant. Yet studies have revealed an astonishing number of biological roles for NO, which occur in many other tissues besides endothelial cells. In fact, it appears that NO serves as one of the body’s most important messenger molecules, as shown by the range of functions identified for this chemical and listed in ■ Table 9-3. As you can see, most areas of the body are influenced by this versatile intercellular messenger molecule.

Endothelial cells release other important chemicals besides NO. **Endothelin**, another endothelial vasoactive substance, causes arteriolar smooth muscle contraction and is one of the most potent vasoconstrictors yet identified. Still other chemicals, released from the endothelium in response to chronic changes in

■ TABLE 9-2 Functions of Endothelial Cells

- Line the blood vessels and heart chambers; serve as a physical barrier between the blood and the remainder of the vessel wall
- Secrete vasoactive substances in response to local chemical and physical changes; these substances cause relaxation (vasodilation) or contraction (vasoconstriction) of the underlying smooth muscle
- Secrete substances that stimulate new vessel growth and proliferation of smooth muscle cells in vessel walls
- Participate in the exchange of materials between the blood and surrounding tissue cells across capillaries through vesicular transport
- Influence formation of platelet plugs, clotting, and clot dissolution (see Chapter 10)
- Participate in the determination of capillary permeability by contracting to vary the size of the pores between adjacent endothelial cells

TABLE 9-3 Functions of Nitric Oxide (NO)

- Causes relaxation of arteriolar smooth muscle. By means of this action, NO plays an important role in controlling blood flow through the tissues and in maintaining mean arterial blood pressure.
- Dilates the arterioles of the penis and clitoris, thus serving as the direct mediator of erection of these reproductive organs. Erection is accomplished by rapid engorgement of these organs with blood.
- Acts as chemical warfare against bacteria and cancer cells via release from macrophages, large phagocytic cells of the immune system
- Interferes with platelet function and blood clotting at sites of vessel damage
- Serves as a novel type of neurotransmitter in the brain and elsewhere
- Plays a role in the changes underlying memory
- By promoting relaxation of digestive tract smooth muscle, helps regulate peristalsis, a type of contraction that pushes digestive tract contents forward
- Relaxes the smooth muscle cells in the airways of the lungs, helping keep these passages open to facilitate movement of air in and out of the lungs
- Modulates the filtering process involved in urine formation
- Directs blood flow to oxygen-starved tissues
- May play a role in relaxation of skeletal muscle

© 2016 Cengage

blood flow to an organ, trigger long-term vascular changes that permanently influence blood flow to a region. Some chemicals, for example, stimulate new vessel growth, a process known as **angiogenesis**.

Local histamine release

Histamine is another local chemical mediator that influences arteriolar smooth muscle, but it is not released in response to local metabolic changes and is not derived from endothelial cells.

Why It Matters Local Heat or Cold Application

Heat application, by causing localized arteriolar vasodilation, is a useful therapeutic agent for promoting increased blood flow to an area. Conversely, applying ice packs to an inflamed area produces vasoconstriction, which reduces swelling by counteracting histamine-induced vasodilation.

Although histamine normally does not participate in controlling blood flow, it is important in certain pathological conditions.

Histamine is synthesized and stored within special connective tissue cells in many organs and in certain types of circulating white blood cells. When organs are injured or during allergic reactions, histamine is released and acts as a paracrine in the damaged region. By promoting relaxation of arteriolar smooth muscle, histamine is the major cause of vasodilation in an injured area. The resultant increase in blood flow into the area produces the redness and contributes to the swelling seen with inflammatory responses (see Chapter 10 for further detail).

Clinical Connections

During exercise, the muscles require more ATP, so blood flow increases to increase the delivery rate of oxygen and ATP precursors such as glucose. However, when blood flow to a muscle is compromised, such as what happens during peripheral artery disease, the muscle turns to anaerobic metabolism. As a consequence, metabolic wastes accumulate and can cause pain and cramping. Within the arteries and arterioles downstream of the plaque, local vasodilating factors accumulate to try to cause dilation and increase blood flow to the skeletal muscle. However, blood flow upstream continues to be restricted due to the atherosclerosis, so supply does not match demand. When John stopped walking, his reduced blood flow to his calves was able to again deliver sufficient oxygen to match muscle activity and to clear out the local mediators of vasodilation.

Local physical influences

Among the physical influences on arteriolar smooth muscle, the effect of temperature changes is exploited clinically, but the chemically mediated response to shear stress and the myogenic response to stretch are most important physiologically. Let's examine each of these effects.

SHEAR STRESS

Because of friction, blood flowing over the surface of the vessel lining creates a longitudinal force, known as **shear stress**, on the endothelial cells. An increase in shear stress causes the endothelial cells to release nitric oxide, which diffuses to the underlying smooth muscle and promotes vasodilation. The resultant increase in arteriolar diameter reduces shear stress in the vessel. In response to shear stress on a long-term basis, endothelial cells orient themselves parallel to the direction of blood flow.

MYOGENIC RESPONSES TO STRETCH

Arteriolar smooth muscle responds to being passively stretched by myogenically increasing its tone via vasoconstriction, thereby acting to resist the initial passive stretch. Conversely, a decrease in arteriolar stretching induces a reduction in myogenic vessel tone by promoting vasodilation. Endothelial-derived vasoactive substances may also contribute to these mechanically induced responses. The extent of passive stretch varies with the volume of blood delivered to the arterioles from the arteries. An increase in mean arterial pressure drives more blood forward into the

arterioles and stretches them further, whereas arterial occlusion blocks blood flow into the arterioles and reduces arteriolar stretch.

Myogenic responses, coupled with metabolically induced responses, are important in reactive hyperaemia and autoregulation, topics to which we now turn our attention.

REACTIVE HYPERAEMIA

When the blood supply to a region is completely occluded, arterioles in the region dilate because of (1) myogenic relaxation, which occurs in response to the diminished stretch accompanying no blood flow, and (2) changes in local chemical composition. Many of the chemical changes that occur in a blood-deprived tissue are the same as those that occur during metabolically induced active hyperaemia. When a tissue's blood supply is blocked, oxygen levels decrease in the deprived tissue; the tissue continues to consume oxygen, but no fresh supplies are being delivered. Meanwhile, the concentrations of carbon dioxide, acid, and other metabolites rise. Even though their production does not increase as it does when a tissue is more active metabolically, these substances accumulate in the tissue when the normal amounts produced are not washed away by blood.

After the occlusion is removed, blood flow to the previously deprived tissue is transiently much higher than normal because the arterioles are widely dilated. This postocclusion increase in blood flow, called **reactive hyperaemia**, can take place in any tissue. Such a response is beneficial for rapidly restoring the local chemical composition to normal. Of course, prolonged blockage of blood flow leads to irreversible tissue damage.

AUTOREGULATION

When mean arterial pressure falls (e.g., because of haemorrhage or a weakened heart), the driving force is reduced, so blood flow to organs decreases. This is a milder version of what happens during vessel occlusion. The resultant changes in local metabolites and the reduced stretch in the arterioles collectively bring about arteriolar dilation to help restore tissue blood flow to normal, despite the reduced driving pressure. On the negative side, widespread arteriolar dilation reduces the mean arterial pressure still further, which aggravates the problem. Conversely, in the presence of sustained elevations in mean arterial pressure (hypertension), local chemical and myogenic influences triggered by the initial increased flow of blood to tissues bring about an increase in arteriolar tone and resistance. This greater degree of vasoconstriction subsequently reduces tissue blood flow toward normal, despite the elevated blood pressure (► Figure 9-13). **Autoregulation** (self-regulation) is the term for these local arteriolar mechanisms that keep tissue blood flow fairly constant despite rather wide deviations in mean arterial driving pressure. Not all organs autoregulate equally. As examples, the brain autoregulates best, the kidneys are good at autoregulation, and skeletal muscle has poor autoregulatory abilities.

Active hyperaemia, reactive hyperaemia, and histamine release all deliberately increase blood flow to a particular tissue for a specific purpose by inducing local arteriolar vasodilation.

► **FIGURE 9-13 Autoregulation of tissue blood flow.** Even though blood flow through a tissue immediately increases in response to a rise in arterial pressure, the tissue blood flow is reduced gradually as a result of autoregulation within the tissue, despite a sustained increase in arterial pressure.

In contrast, autoregulation is a means by which each tissue resists alterations in its own blood flow secondary to changes in mean arterial pressure by making appropriate adjustments in arteriolar radius.

As an example of autoregulation, consider the effects of postural changes on blood flow to the brain. When you suddenly go from lying down to standing up, the body undergoes several responses in order to maintain blood flow to the brain. Within the brain itself, this sudden decrease in pressure, and thus blood flow, cause arteries and arterioles to constrict to increase pressure and maintain blood flow. This compensatory response reverses as systemic arterial pressure stabilizes to the new posture. Although this example has been oversimplified, it does highlight the ability of an organ to autoregulate its blood flow to ensure that there is a constant supply of oxygen.

This completes our discussion of the local control of arteriolar radius. Now let's examine extrinsic control of arteriolar radius.

Extrinsic sympathetic control of arteriolar radius

Extrinsic control of arteriolar radius includes both neural and hormonal influences, the effects of the sympathetic nervous system being the most important. Sympathetic nerve fibres supply arteriolar smooth muscle everywhere in the systemic circulation, except in the brain. Recall that a certain level of ongoing sympathetic activity contributes to vascular tone. Increased sympathetic activity produces generalized arteriolar vasoconstriction, whereas decreased sympathetic activity leads to generalized arteriolar vasodilation. These widespread changes in arteriolar resistance bring about changes in mean arterial pressure because of their influence on total peripheral resistance, as we describe next.

INFLUENCE OF TOTAL PERIPHERAL RESISTANCE ON MEAN ARTERIAL PRESSURE

To find the effect of changes in arteriolar resistance on mean arterial pressure, the formula $F = \Delta P/R$ applies to the entire circulation as well as to a single vessel:

- F : Looking at the circulatory system as a whole, flow (F) through all the vessels in either the systemic or pulmonary circulation is equal to the cardiac output.
- P : The pressure gradient (ΔP) for the entire systemic circulation is the *mean arterial pressure*. (ΔP equals the difference in pressure between the beginning and the end of the systemic circulatory system. The beginning pressure is the mean arterial pressure as the blood leaves the left ventricle at an average of 93 mmHg. The end pressure in the right atrium is 0 mmHg. Therefore, $\Delta P = 93 \text{ mmHg} - 0 \text{ mmHg} = 93 \text{ mmHg}$, which is equivalent to the mean arterial pressure.)
- R : The total resistance (R) offered by all the systemic peripheral vessels together is the **total peripheral resistance**. By far the greatest percentage of the total peripheral resistance is due to arteriolar resistance, because arterioles are the primary resistance vessels.

Therefore, for the entire systemic circulation, rearranging

$$F = \Delta P/R$$

to

$$\Delta P = F \times R$$

gives us the equation

$$\text{Mean arterial pressure} = \text{cardiac output} \times \text{total peripheral resistance}$$

Thus, the extent of total peripheral resistance offered collectively by all the systemic arterioles influences the mean arterial pressure immensely. A dam provides an analogy to this relationship. At the same time a dam restricts the flow of water downstream, it increases the pressure upstream by elevating the water level in the reservoir behind the dam. Similarly, generalized, sympathetically induced vasoconstriction reduces blood flow downstream to the organs while elevating the upstream mean arterial pressure, thereby increasing the main driving force for blood flow to all the organs.

These effects seem counterproductive. Why increase the driving force for flow to the organs by increasing arterial blood pressure while reducing flow to the organs by narrowing the vessels supplying them? In effect, the sympathetically induced arteriolar responses help maintain the appropriate driving pressure head (i.e., the mean arterial pressure) to all organs. The extent to which each organ actually receives blood flow is determined by local arteriolar adjustments that override the sympathetic constrictor effect. If all arterioles were dilated, total tissue perfusion would be greater than cardiac output, resulting in blood pressure to fall substantially, so there would not be an adequate driving force for blood flow. An analogy is the pressure head for water in the pipes in your home. If the water pressure is adequate, you can selectively obtain satisfactory water flow at any of the faucets by turning the appropriate handle to the open position. If the water pressure in

the pipes is too low, however, you cannot obtain satisfactory flow at any faucet, even if you turn the handle to the maximally open position. So tonic sympathetic activity constricts most vessels (with the exception of those in the brain) and thereby helps maintain a pressure head, which organs can draw upon as needed by means of local mechanisms that control arteriolar radius.

NOREPINEPHRINE'S INFLUENCE ON ARTERIOLAR SMOOTH MUSCLE

The norepinephrine released from sympathetic nerve endings combines with α_1 -adrenergic receptors on arteriolar smooth muscle to bring about vasoconstriction (p. 193). Cerebral (brain) arterioles are the only ones that do not have α_1 receptors, so no vasoconstriction occurs in the brain. It is important that cerebral arterioles are not constricted by neural influences, because brain blood flow must remain constant to meet the brain's continual need for oxygen, no matter what is going on elsewhere in the body. Cerebral vessels are almost entirely controlled by local mechanisms that maintain a constant blood flow to support a constant level of brain metabolic activity. In fact, reflex vasoconstrictor activity in the remainder of the cardiovascular system is aimed at maintaining an adequate pressure head for blood flow to the vital brain.

Sympathetic activity therefore contributes in an important way to maintaining mean arterial pressure; it does so by ensuring an adequate driving force for blood flow to the brain at the expense of organs that can better withstand reduced blood flow. Other organs that really need additional blood, such as active muscles (including active heart muscle), obtain it through local controls that override the sympathetic effect.

LOCAL CONTROLS OVERRIDING SYMPATHETIC VASOCONSTRICTION

Skeletal and cardiac muscles have the most powerful local control mechanisms with which to override generalized sympathetic vasoconstriction. For example, if you are pedalling a bicycle, the increased activity in the skeletal muscles of your legs brings about an overriding local, metabolically induced vasodilation in those particular muscles, despite the generalized sympathetic vasoconstriction that accompanies exercise. As a result, more blood flows through your leg muscles but not through your inactive arm muscles.

NO PARASYMPATHETIC INNERVATION TO ARTERIOLES

There is no significant parasympathetic innervation to arterioles, with the exception of the abundant parasympathetic vasodilator supply to the arterioles of the penis and clitoris. The rapid, profuse vasodilation induced by parasympathetic stimulation in these organs (by means of promoting release of NO) is largely responsible for accomplishing erection. Vasodilation elsewhere is produced by decreasing sympathetic vasoconstrictor activity below its tonic level. When mean arterial pressure rises above normal, reflex reduction in sympathetic vasoconstrictor activity accomplishes generalized arteriolar vasodilation to help bring the driving pressure down toward normal.

The medullary cardiovascular control centre

The main region of the brain that adjusts sympathetic output to the arterioles is the **cardiovascular control centre** in the medulla of the brain stem. This is the integrating centre for blood pressure regulation (described in Section 8.6). Several other brain regions also influence blood distribution, the most notable being the hypothalamus, which, as part of its temperature-regulating function, controls blood flow to the skin to adjust heat loss to the environment.

In addition to neural reflex activity, several hormones also extrinsically influence arteriolar radius. These hormones include the adrenal medullary hormones *epinephrine* and *norepinephrine*, which generally reinforce the sympathetic nervous system in most organs, as well as *vasopressin (ADH)* and *angiotensin II*, which are important in controlling fluid balance.

INFLUENCE OF EPINEPHRINE AND NOREPINEPHRINE

Sympathetic stimulation of the adrenal medulla causes this endocrine gland to release epinephrine and norepinephrine. Adrenal medullary norepinephrine combines with the same α_1 receptors as sympathetically released norepinephrine to produce generalized vasoconstriction. However, epinephrine, the more abundant of the adrenal medullary hormones, combines with both β_2 and α_1 receptors, but has a much greater affinity for the β_2 receptors (Table 9-4). Activation of β_2 receptors produces vasodilation, but not all tissues have β_2 receptors; they are most abundant in the arterioles of the heart and skeletal muscles. During sympathetic discharge, the released epinephrine combines with the β_2 receptors in the heart and skeletal muscles to reinforce local vasodilatory mechanisms in these tissues. Arterioles in digestive organs and kidneys, in contrast, are equipped only with α_1 receptors. Therefore, the arterioles of these organs undergo more profound vasoconstriction during generalized sympathetic discharge than those in the heart and skeletal muscle do. Lacking β_2 receptors, the digestive organs and kidneys do not experience an overriding vasodilatory response on top of the α_1 receptor-induced vasoconstriction.

INFLUENCE OF VASOPRESSIN AND ANGIOTENSIN II

The two other hormones that extrinsically influence arteriolar tone are vasopressin and angiotensin II. Vasopressin is primarily involved in maintaining water balance by regulating the amount of water the kidneys retain for the body during urine formation (p. 592). Angiotensin II is part of a hormonal pathway, the *renin-angiotensin-aldosterone system*, which is important in regulating the body's salt balance. This pathway promotes salt conservation during urine formation and also leads to water retention, because salt exerts a water-holding osmotic effect in the ECF (p. 575). Consequently, both these hormones play important roles in maintaining the body's fluid balance, which in turn is an important determinant of plasma volume and blood pressure.

In addition, both vasopressin and angiotensin II are potent vasoconstrictors. Their role in this regard is especially crucial during haemorrhage. A sudden loss of blood reduces the plasma volume, which triggers increased secretion of both these hormones to help restore plasma volume. Their vasoconstrictor effects also help maintain blood pressure despite abrupt loss of plasma volume. (The functions and control of these hormones are discussed more thoroughly in Chapters 5 and 6.)

This completes our discussion of the various factors that affect total peripheral resistance, the most important of which are controlled adjustments in arteriolar radius. These factors are summarized in Figure 9-14.

We now turn our attention to the next vessels in the vascular tree, the capillaries.

9.4 | Capillaries

Capillaries branch extensively to bring blood within the reach of every cell and, therefore, are considered the primary site for exchange of materials between blood and tissue cells. However, it is important to note that the entire vasculature is a continuum and does not abruptly change

TABLE 9-4 Arteriolar Smooth Muscle Adrenergic Receptors

CHARACTERISTIC	RECEPTOR TYPE	
	α_1	β_2
Location of the Receptor	All arteriolar smooth muscle except in the brain	Arteriolar smooth muscle in the heart and skeletal muscles
Chemical Mediator	Norepinephrine from sympathetic fibres and the adrenal medulla Epinephrine from the adrenal medulla (less affinity for this receptor)	Epinephrine from the adrenal medulla (greater affinity for this receptor)
Arteriolar Smooth Muscle Response	Vasoconstriction	Vasodilation

► **FIGURE 9-14 Factors affecting total peripheral resistance.** The primary determinant of total peripheral resistance is the adjustable arteriolar radius. Two major categories of factors influence arteriolar radius: (1) local (intrinsic) control, which is primarily important in matching blood flow through a tissue with the tissue's metabolic needs and is mediated by local factors acting on the arteriolar smooth muscle; and (2) extrinsic control, which is important in regulating blood pressure and is mediated primarily by sympathetic influence on arteriolar smooth muscle.

from one vascular type to another. Consequently, some exchange takes place across the other microcirculatory vessels, especially the postcapillary venules. When the term *capillary exchange* is used, it tacitly refers to all exchange at the microcirculatory level, the majority of which occurs across the capillaries.

Capillaries: Sites of exchange

There are no carrier-mediated transport systems across capillaries, with the exception of those in the brain that play a role in the blood–brain barrier (p. 100). Materials are exchanged across capillary walls mainly by diffusion.

FACTORS THAT ENHANCE DIFFUSION ACROSS CAPILLARIES

Capillaries are ideally suited to enhance diffusion. They minimize diffusion distances while maximizing surface area and time available for exchange, as follows:

1. Diffusing molecules have only a short distance to travel between blood and surrounding cells because of the thin capillary wall and small capillary diameter, coupled with the close proximity of every cell to a capillary. This short distance is important because the rate of diffusion slows down as the diffusion distance increases.
 - a. Capillary walls are very thin (1 μm in thickness; in contrast, the diameter of a human hair is 100 μm). Capillaries consist of only a single layer of flat endothelial cells—essentially the lining of the other vessel types. No smooth muscle or connective tissue is present (see Table 9-1).
 - b. Each capillary is so narrow (7 μm average diameter) that red blood cells (8 μm diameter) have to squeeze through single file (Figure 9-15b). Consequently, plasma contents are either in direct contact with the inside of the capillary wall or are only a short diffusing distance from it.
 - c. Researchers estimate that because of extensive capillary branching, no cell is farther than 0.01 cm (4/1000 in.) from a capillary.
2. Because capillaries are distributed in such incredible numbers (estimates range from 10 billion to 40 billion capillaries), a tremendous total surface area is available for exchange (an estimated 600 m^2). Despite this large number of capillaries, at any point in time they contain only 5 percent of the total blood volume (250 mL out of a total of 5000 mL). As a result, a small volume of blood is exposed to an extensive surface area. If all the capillary surfaces were stretched out in a flat sheet and the volume of blood contained within the capillaries were spread over the top, this would be roughly equivalent to spreading a half pint (237 mL) of paint over the floor of a high school gymnasium. Imagine how thin the paint layer would be!
3. Blood flows more slowly in the capillaries than elsewhere in the circulatory system. The extensive capillary branching is responsible for this slow velocity of blood flow through the capillaries. Let's see why blood slows down in the capillaries.

SLOW VELOCITY OF FLOW THROUGH CAPILLARIES

First, we need to clarify a potentially confusing point. The term *flow* can be used in two different contexts—flow rate and velocity of flow. The *flow rate* refers to the *volume* of blood per unit of time flowing through a given segment of the circulatory system (this is the flow we have been talking about in relation to the pressure gradient and resistance). The *velocity of flow* is the linear *speed*, or distance per unit of time, with which blood flows forward through a given segment of the circulatory system. Because the circulatory system is a closed system, the volume of blood flowing through any level of the system must equal the cardiac

FIGURE 9-15 Capillary anatomy. (a) Electron micrograph of a cross-section of a capillary. The capillary wall consists of a single layer of endothelial cells. The nucleus of one of these cells is shown. (b) Photograph of a capillary bed. The capillaries are so narrow that the red blood cells must pass through single file.

output. For example, if the heart pumps out 5 L of blood per minute, and 5 L/min return to the heart, then 5 L/min must flow through the arteries, arterioles, capillaries, and veins. Therefore, the flow rate is the same at all levels of the circulatory system.

However, the velocity with which blood flows through the different segments of the vascular tree varies, because velocity of flow is inversely proportional to the total cross-sectional area of all the vessels at any given level of the circulatory system. Even though the cross-sectional area of each capillary is extremely small compared to that of the large aorta, the total cross-sectional area of all capillaries added together is about 1300 times greater than the cross-sectional area of the aorta—because there are so many capillaries. Accordingly, blood slows considerably as it passes through the capillaries (Figure 9-16). This slow velocity allows adequate time for exchange of nutrients and metabolic end products between blood and tissue cells. As the

► **FIGURE 9-16** Comparison of blood flow rate and velocity of flow in relation to total cross-sectional area. The blood flow rate (red curve) is identical through all levels of the circulatory system and is equal to the cardiac output (5 L/min at rest). The velocity of flow (purple curve) varies throughout the vascular tree and is inversely proportional to the total cross-sectional area (green curve) of all the vessels at a given level. Note that the velocity of flow is slowest in the capillaries, which have the largest total cross-sectional area.

capillaries rejoin to form veins, the total cross-sectional area is once again reduced, and the velocity of blood flow increases as blood returns to the heart.

As an analogy, consider a river (the arterial system) that widens into a lake (the capillaries), then narrows into a river again (the venous system) (► Figure 9-17). The flow rate is the same throughout the length of this body of water; that is, identical volumes of water are flowing past all the points along the bank of the river and lake. However, the velocity of flow is slower in the wide lake than in the narrow river because the identical

► **FIGURE 9-17** Relationship between total cross-sectional area and velocity of flow. The three dark blue areas represent equal volumes of water. During one minute, this volume of water moves forward from points A to points C. Therefore, an identical volume of water flows past points A1, B1, and B3 during this minute; that is, the flow rate is the same at all points along the length of this body of water. However, during that minute the identical volume of water moves forward a much shorter distance in the wide lake (A2 to C2) than in the much narrower river (A1 to C1 and A3 to C3). Thus, the velocity of flow is much slower in the capillaries than in the arterial and venous systems.

volumes of water, now spread out over a larger cross-sectional area, move forward a much shorter distance in the wide lake than in the narrow river during a given period of time. You could readily observe the forward movement of water in the swift-flowing river, but the forward motion of water in the lake would be unnoticeable.

As well, because of the capillaries' tremendous total cross-sectional area, the resistance offered by all the capillaries is much lower than that offered by all the arterioles, even though each capillary has a smaller radius than each arteriole. For this reason, the arterioles contribute more to total peripheral resistance. Furthermore, arteriolar calibre (and, accordingly, resistance) is subject to control, whereas capillary calibre cannot be adjusted.

Capillary pores

Diffusion across capillary walls also depends on the walls' permeability to the materials being exchanged. The endothelial cells forming the capillary walls fit together in a jigsaw-puzzle fashion, but the closeness of the fit varies considerably between organs. In most capillaries, narrow, water-filled gaps, or **pores**, lie at the junctions between the cells (► Figure 9-18). These pores permit passage of small water-soluble substances. Lipid-soluble substances, such as oxygen and carbon dioxide, can readily pass through the endothelial cells themselves by dissolving in the lipid bilayer barrier.

The size of the capillary pores varies from organ to organ. At one extreme, the endothelial cells in brain capillaries are joined by tight junctions so that pores are nonexistent. These junctions prevent transcapillary passage of materials between the cells and thus constitute part of the protective blood-brain barrier (p. 100). In most tissues, small, water-soluble substances, such as ions, glucose, and amino acids, can readily pass through the

© 2016 Cengage

FIGURE 9-18 Exchanges across the capillary wall. (a) Slit-like gaps between adjacent endothelial cells form pores within the capillary wall. (b) As depicted in this schematic representation of a cross-section of a capillary wall, small water-soluble substances are exchanged between the plasma and the interstitial fluid by passing through the water-filled pores, whereas lipid-soluble substances are exchanged across the capillary wall by passing through the endothelial cells. Proteins to be moved across are exchanged by vesicular transport. Plasma proteins generally cannot escape from the plasma across the capillary wall.

water-filled pores, but large, non-lipid-soluble materials that cannot fit through the pores, such as plasma proteins, are kept from passing. At the other extreme, liver capillaries have such large pores that even proteins pass through readily. This is adaptive, because the liver's functions include synthesis of plasma proteins and the metabolism of protein-bound substances, such as cholesterol. These proteins must all pass through the liver's capillary walls. The leakiness of various capillary beds is therefore a function of how tightly the endothelial cells are joined, which varies according to the different organs' needs.

Scientists traditionally considered the capillary wall a passive sieve, like a brick wall with permanent gaps in the mortar acting as pores. Recent studies, however, suggest that endothelial cells can actively change to regulate capillary permeability; that is, in response to appropriate signals, the "bricks" can readjust themselves to vary the size of the holes. So the degree of leakiness does not necessarily remain constant for a given capillary bed. For example, histamine increases capillary permeability by triggering contractile responses in endothelial cells to widen the intercellular gaps. This is not a muscular contraction, because no smooth muscle cells are present in capillaries. It is due to an actin-myosin contractile apparatus in the nonmuscular capillary endothelial cells. Because of these enlarged pores, the affected capillary wall is leakier. As a result, normally retained plasma proteins escape into the surrounding tissue, where they exert an osmotic effect. Along with histamine-induced vasodilation, the resulting additional local fluid retention contributes to inflammatory swelling.

Vesicular transport also plays a limited role in the passage of materials across the capillary wall. Large non-lipid-soluble molecules, such as protein hormones, that must be exchanged between blood and surrounding tissues are transported from one side of the capillary wall to the other in endocytotic-exocytotic vesicles (p. 46).

Capillaries under resting conditions

The branching and reconverging arrangement within capillary beds varies somewhat, depending on the tissue. Capillaries typically branch either directly from an arteriole or from a thoroughfare channel known as a **metarteriole**, which runs between an arteriole and a venule. Likewise, capillaries may rejoin at either a venule or a metarteriole (Figure 9-19a).

Unlike the true capillaries within a capillary bed, metarterioles are sparsely surrounded by wisps of spiralling smooth muscle cells. These cells also form **precapillary sphincters**, each of which consists of a ring of smooth muscle around the entrance to a capillary as it arises from a metarteriole. However, it is important to note that although generally accepted, the existence of precapillary sphincters in humans has not been conclusively established.

ROLE OF PRECAPILLARY SPHINCTERS

Precapillary sphincters are not innervated, but they have a high degree of myogenic tone and are sensitive to local metabolic changes. They act as stopcocks to control blood flow through

(a) Sphincters relaxed

(b) Sphincters contracted

FIGURE 9-19 Capillary bed. Capillaries branch either directly from an arteriole or from a metarteriole, a thoroughfare channel between an arteriole and venule. Capillaries rejoin at either a venule or a metarteriole. Smooth muscle cells form precapillary sphincters that encircle capillaries as they arise from the metarteriole. (a) When the precapillary sphincters are relaxed, blood flows through the entire capillary bed. (b) When the precapillary sphincters are contracted, blood flows only through the metarteriole, bypassing the capillary bed.

the particular capillary that each one guards. Arterioles perform a similar function for a small group of capillaries. Capillaries themselves have no smooth muscle, so they cannot actively participate in regulating their own blood flow.

Generally, tissues that are more metabolically active have a greater density of capillaries. For example, skeletal muscle has more capillaries (greater density) than the tendons that join muscle to bone. Only about 10 percent of the precapillary sphincters in a resting muscle are open at any moment, so blood flow through the muscle is reduced to about 10 percent of maximum, and the rest flows through the metarterioles (Figure 9-19b). As muscle metabolism increases, the need for oxygen and the production of carbon dioxide increase, and other chemical concentrations change, thus facilitating the relaxation of precapillary sphincters and arterioles in that region. Restoration of the chemical concentrations to normal as a result of increased blood flow to that region removes the impetus for vasodilation, so the precapillary sphincters close once again, and the arterioles return to normal tone. In this way, blood flow through any given capillary is often intermittent due to arteriolar and precapillary sphincter action working in concert.

When the muscle as a whole becomes more active, a greater percentage of the precapillary sphincters relax, simultaneously opening up more capillary beds, while concurrent arteriolar vasodilation increases total flow to the organ. As a result of more blood flowing through more open capillaries, the total

volume and surface area available for exchange increase, and the diffusion distance between the cells and an open capillary decreases (Figure 9-20). Therefore, blood flow through a particular tissue (assuming a constant blood pressure) is regulated by (1) the degree of resistance offered by the arterioles in the organ, controlled by sympathetic activity and local factors; and (2) the number of open capillaries, controlled by action of the same local metabolic factors on precapillary sphincters.

Interstitial fluid: A passive intermediary

Exchanges between blood and tissue cells are not made directly. Interstitial fluid, the true internal environment in immediate contact with the cells, acts as the go-between. Only 20 percent of the ECF circulates as plasma. The remaining 80 percent consists of interstitial fluid, which bathes all the cells in the body. Cells exchange materials directly with interstitial fluid, with the type and extent of exchange governed by the properties of cellular plasma membranes. Movement across the plasma membrane may be either passive (i.e., by diffusion down electrochemical gradients or by facilitated diffusion) or active (i.e., by active carrier-mediated transport or by vesicular transport) (see Table 2-5).

In contrast, exchanges across the capillary wall between plasma and interstitial fluid are largely passive. The only transport across this barrier that requires energy is the limited vesicular transport. Because capillary walls are highly permeable,

► **FIGURE 9-20** Complementary action of precapillary sphincters and arterioles in adjusting blood flow through a tissue in response to changing metabolic needs

exchange is so thorough that the interstitial fluid takes on essentially the same composition as incoming arterial blood, with the exception of the large plasma proteins that usually do not escape from the blood. Therefore, when we speak of exchanges between blood and tissue cells, we tacitly include interstitial fluid as a passive intermediary.

Exchanges between blood and surrounding tissues across the capillary walls are accomplished in two ways: (1) passive diffusion down concentration gradients, the primary mechanism for exchanging individual solutes; and (2) bulk flow, a process that fills the totally different function of determining the distribution of the ECF volume between the vascular and interstitial fluid compartments. Now let's examine each of these mechanisms in more detail, starting with diffusion.

Diffusion across the capillary walls

There are no carrier-mediated transport systems in most capillary walls; therefore, solutes cross primarily by diffusion down concentration gradients. The chemical composition of arterial blood is carefully regulated to maintain the concentrations of individual solutes at levels that promote each solute's movement

in the appropriate direction across the capillary walls. The reconditioning organs continuously add nutrients and oxygen and remove carbon dioxide and other wastes as blood passes through them. Meanwhile, cells constantly use up supplies and generate metabolic wastes. As cells use up oxygen and glucose, the blood constantly brings in fresh supplies of these vital materials, maintaining concentration gradients that favour the net diffusion of these substances from blood to cells. Simultaneously, ongoing net diffusion of carbon dioxide and other metabolic wastes from cells to blood is maintained by the continual production of these wastes at the cell level and by their constant removal by the circulating blood (► Figure 9-21).

Because the capillary wall does not limit the passage of any constituent except plasma proteins, the extent of exchanges for each solute is independently determined by the magnitude of its concentration gradient between blood and surrounding cells. As cells increase their level of activity, they use up more oxygen and produce more carbon dioxide, among other things. This creates larger concentration gradients for oxygen and carbon dioxide between cells and blood, so more oxygen diffuses out of the blood into the cells, and more carbon dioxide proceeds in the opposite direction to help support the increased metabolic activity.

► **FIGURE 9-21** Independent exchange of individual solutes down their own concentration gradients across the capillary wall

Bulk flow across the capillary walls

The second means by which exchange is accomplished across capillary walls is bulk flow. A volume of protein-free plasma actually filters out of the capillary, mixes with the surrounding interstitial fluid, and then is reabsorbed. This process is called **bulk flow**, because the various constituents of the fluid are moving together in bulk, or as a unit, in contrast to the discrete diffusion of individual solutes down concentration gradients.

The capillary wall acts like a sieve, with fluid moving through its water-filled pores. When pressure inside the capillary exceeds pressure on the outside, fluid is pushed out through the pores in a process known as **ultrafiltration**. Due to the pores' filtering effect, most plasma proteins are retained on the inside during this process, although a few do escape. All other constituents in the plasma are dragged as a unit along with the volume of fluid leaving the capillary, so the filtrate is essentially a protein-free plasma. When inward-driving pressures exceed outward pressures across the capillary wall, net inward movement of fluid from the interstitial fluid into the capillaries takes place through the pores, a process known as **reabsorption**.

FORCES INFLUENCING BULK FLOW

Bulk flow occurs because of differences in the hydrostatic and colloid osmotic pressures between plasma and interstitial fluid. These pressures are what are called the *Starling forces* and are used in the Starling equation that defines the movement of fluid across a capillary membrane. Even though pressure differences exist between plasma and surrounding fluid elsewhere in the circulatory system, only the capillaries have pores that let fluids pass through. Four forces influence fluid movement across the capillary wall (► Figure 9-22):

1. **Capillary blood pressure (P_C)** is the fluid or hydrostatic pressure exerted on the inside of the capillary walls by blood. This pressure tends to force fluid *out of* the capillaries into the interstitial fluid. By the level of the capillaries, blood pressure has dropped substantially because of frictional losses in pressure in the high-resistance

arterioles upstream. On average, the hydrostatic pressure is 37 mmHg at the arteriolar end of a tissue capillary (compared with a mean arterial pressure of 93 mmHg). It declines even further, to 17 mmHg, at the capillary's venular end because of further frictional loss coupled with the exit of fluid through ultrafiltration along the capillary's length (see ► Figure 9-9).

2. **Plasma-colloid osmotic pressure (π_P)**, also known as *oncotic pressure*, is a force caused by colloidal dispersion of plasma proteins; it encourages fluid movement *into* the capillaries. Because plasma proteins remain in the plasma rather than entering the interstitial fluid, a protein concentration difference exists between plasma and interstitial fluid. Accordingly, there is also a water concentration difference between these two regions. Plasma has a higher protein concentration and a lower water concentration than interstitial fluid does. This difference exerts an osmotic effect that tends to move water from the area of higher water concentration in interstitial fluid to the area of lower water concentration (or higher protein concentration) in plasma (p. 38). The other plasma constituents do not exert an osmotic effect, because they readily pass through the capillary wall, so their concentrations are equal in plasma and interstitial fluid. Plasma-colloid osmotic pressure averages 25 mmHg.
3. **Interstitial fluid hydrostatic pressure (P_{IF})** is the fluid pressure exerted on the outside of the capillary wall by interstitial fluid. This pressure tends to force fluid *into* the capillaries. Because of difficulties encountered in measuring interstitial fluid hydrostatic pressure, the actual value of the pressure is a controversial issue. It is either at, slightly above, or slightly below atmospheric pressure. For purposes of illustration, we will say it is 1 mmHg above atmospheric pressure.
4. **Interstitial fluid-colloid osmotic pressure (π_{IF})** is another force that does not normally contribute significantly to bulk flow. The small fraction of plasma proteins

► **FIGURE 9-22 Bulk flow across the capillary wall.** Schematic representation of ultrafiltration and reabsorption as a result of imbalances in the physical forces acting across the capillary wall

that leak across the capillary walls into the interstitial spaces are normally returned to the blood by means of the lymphatic system. Therefore, the protein concentration in the interstitial fluid is extremely low, and the interstitial fluid–colloid osmotic pressure is very close to zero. If plasma proteins pathologically leak into the interstitial fluid, however, as they do when histamine widens the capillary pores during tissue injury, the leaked proteins exert an osmotic effect that tends to promote movement of fluid *out* of the capillaries into the interstitial fluid.

Therefore, the two pressures that tend to force fluid out of the capillary are capillary blood pressure and interstitial fluid–colloid osmotic pressure. The two opposing pressures that tend to force fluid into the capillary are plasma–colloid osmotic pressure and interstitial fluid hydrostatic pressure. Now let’s analyze the fluid movement that occurs across a capillary wall because of imbalances in these opposing physical forces (► Figure 9-22).

NET EXCHANGE OF FLUID ACROSS THE CAPILLARY WALL

Net exchange at a given point across the capillary wall can be calculated using the following:

$$\text{Net exchange pressure} = (P_c + \pi_{IF}) - (\pi_p + P_{IF})$$

(outward pressure) (inward pressure)

A positive net exchange pressure (when the outward pressure exceeds the inward pressure) represents a filtration pressure. A negative net exchange pressure (when the inward pressure exceeds the outward pressure) represents a reabsorption pressure.

At the arteriolar end of the capillary, the outward pressure totals 37 mmHg, whereas the inward pressure totals 26 mmHg, for a net outward pressure of 11 mmHg. Filtration takes place at the beginning of the capillary as this outward pressure gradient forces a protein-free filtrate through the capillary pores.

By the time the venular end of the capillary is reached, the capillary blood pressure has dropped, but the other pressures have remained essentially constant. At this point, the outward pressure has fallen to a total of 17 mmHg, whereas the total inward pressure is still 26 mmHg, for a net inward pressure of 9 mmHg. Reabsorption of fluid takes place as this inward pressure gradient forces fluid back into the capillary at its venular end.

Filtration and reabsorption, collectively known as *bulk flow*, are thus due to a shift in the balance between the passive physical forces acting across the capillary wall. No active forces or local energy expenditures are involved in the bulk exchange of fluid between the plasma and surrounding interstitial fluid. With only minor contributions from the interstitial fluid forces, filtration occurs at the beginning of the capillary because capillary blood pressure exceeds plasma–colloid osmotic pressure, whereas by the end of the capillary, reabsorption takes place because blood pressure has fallen below osmotic pressure.

It is important to realize that we have taken “snapshots” at two points—at the beginning and at the end—in a hypothetical capillary. Actually, blood pressure gradually diminishes along

► FIGURE 9-23 Net filtration and net reabsorption along the vessel

length. The inward pressure ($\pi_p + P_{IF}$) remains constant throughout the length of the capillary, whereas the outward pressure ($P_c + \pi_{IF}$) progressively declines throughout the capillary’s length. In the first half of the vessel, where the declining outward pressure still exceeds the constant inward pressure, progressively diminishing quantities of fluid are filtered out (*upward red arrow*). In the last half of the vessel, the progressively increasing quantities of fluid are reabsorbed (*downward blue arrow*) as the declining outward pressure falls farther below the constant inward pressure.

the length of the capillary, so that progressively diminishing quantities of fluid are filtered out in the first half of the vessel and progressively increasing quantities of fluid are reabsorbed in the last half (► Figure 9-23). Even this situation is idealized. The pressures used in this figure are average values and controversial at that. Some capillaries have such high blood pressure that filtration actually occurs throughout their entire length, whereas others have such low hydrostatic pressure that reabsorption takes place throughout their length.

In fact, a recent theory that has received considerable attention is that net filtration occurs throughout the length of all *open* capillaries, whereas net reabsorption occurs throughout the length of all *closed* capillaries. According to this theory, when the precapillary sphincter is relaxed, capillary blood pressure exceeds the plasma osmotic pressure even at the venular end of the capillary, thereby promoting filtration throughout the length. When the precapillary sphincter is closed, the reduction in blood flow through the capillary diminishes capillary blood pressure below the plasma osmotic pressure even at the beginning of the capillary, so reabsorption takes place all along the capillary. Whichever mechanism is involved, the net effect is the same. A protein-free filtrate exits the capillaries and is ultimately reabsorbed.

ROLE OF BULK FLOW

Bulk flow does not play an important role in the exchange of individual solutes between blood and tissues. This is because the quantity of solutes moved across the capillary wall by bulk flow is extremely small compared with the much larger transfer of solutes by diffusion. Thus, ultrafiltration and reabsorption are not important in the exchange of nutrients and wastes. Bulk flow is extremely important, however, in regulating the distribution of ECF between the plasma and interstitial fluid. Maintenance of proper arterial blood pressure depends in part on an appropriate volume of circulating blood. If plasma volume is reduced

(e.g., by haemorrhage), blood pressure falls. The resultant lowering of capillary blood pressure alters the balance of forces across the capillary walls. Because the net outward pressure is decreased while the net inward pressure remains unchanged, extra fluid is shifted from the interstitial compartment into the plasma as a result of reduced filtration and increased reabsorption. The extra fluid soaked up from the interstitial fluid provides additional fluid for the plasma, temporarily compensating for the loss of blood. Meanwhile, reflex mechanisms acting on the heart and blood vessels also come into play to help maintain blood pressure until long-term mechanisms, such as thirst (and its satisfaction) and reduction of urinary output, can restore the fluid volume to completely compensate for the loss.

Conversely, if the plasma volume becomes overexpanded, as with excessive fluid intake, the resulting rise in capillary blood pressure forces extra fluid from the capillaries into the interstitial fluid, temporarily relieving the expanded plasma volume until the excess fluid can be eliminated from the body by long-term measures, such as increased urinary output.

These internal fluid shifts between the two ECF compartments occur automatically and immediately whenever the balance of forces acting across the capillary walls is changed; they provide a temporary mechanism to help keep plasma volume fairly constant. In the process of restoring plasma volume to an appropriate level, interstitial fluid volume fluctuates, but it is much more important that plasma volume be kept constant, to ensure that the circulatory system functions effectively.

The lymphatic system

Even under normal circumstances, slightly more fluid is filtered out of the capillaries into the interstitial fluid than is reabsorbed from the interstitial fluid back into the plasma. The extra fluid filtered out as a result of this filtration–reabsorption imbalance is picked up by the **lymphatic system**. This extensive network of one-way vessels provides an accessory route by which fluid can be returned from the interstitial fluid to the blood. The lymphatic system functions much like a storm sewer that picks up and carries away excess rainwater so that the water does not accumulate and flood an area.

PICKUP AND FLOW OF LYMPH

Small, blind-ended, terminal lymph vessels known as **initial lymphatics** permeate almost every tissue of the body (► Figure 9-24a). The endothelial cells forming the walls of initial lymphatics slightly overlap like shingles on a roof, with their overlapping edges being free instead of attached to the surrounding cells. This arrangement creates one-way, valve-like openings in the vessel wall. Fluid pressure on the outside of the vessel pushes the innermost edge of a pair of overlapping edges inward, creating a gap between the edges (i.e., opening the valve). This opening permits interstitial fluid to enter (► Figure 9-24b). Once interstitial fluid enters a lymphatic vessel, it is called **lymph**. Fluid pressure on the inside forces the overlapping edges together, closing the valves so that lymph does not escape. These lymphatic valvelike openings are much larger than the pores in blood capillaries. Consequently, large particles in the

Fluid pressure on the outside of the vessel pushes the endothelial cell's free edge inward, permitting entrance of interstitial fluid (now lymph).

Fluid pressure on the inside of the vessel forces the overlapping edges together so that lymph cannot escape.

► **FIGURE 9-24 Initial lymphatics.** (a) Relationship between initial lymphatics and blood capillaries. Blind-ended initial lymphatics pick up excess fluid that has been filtered by blood capillaries and return it to the venous system in the chest. (b) Arrangement of endothelial cells in an initial lymphatic. Note that the overlapping edges of the endothelial cells create valvelike openings in the vessel wall.

interstitial fluid, such as escaped plasma proteins and bacteria, can gain access to initial lymphatics but are excluded from blood capillaries.

Initial lymphatics converge to form larger and larger **lymph vessels**, which eventually empty into the venous system near where the blood enters the right atrium (► Figure 9-25a). Because there is no “lymphatic heart” to provide driving pressure, you may wonder how lymph is directed from the tissues toward the venous system in the thoracic cavity. Lymph flow is accomplished by two mechanisms. First, lymph vessels beyond the initial lymphatics are surrounded by smooth muscle, which contracts rhythmically as a result of myogenic activity. When this muscle is stretched because

the vessel is distended with lymph, the muscle inherently contracts more forcefully, pushing the lymph through the vessel. This intrinsic “lymph pump” is the major force for propelling lymph. Stimulation of lymphatic smooth muscle by the sympathetic nervous system further increases the pumping activity of the lymph vessels. Second, because lymph vessels lie between skeletal muscles, contraction of these muscles squeezes the lymph out of the vessels. One-way valves spaced at intervals within the lymph vessels direct the flow of lymph toward its venous outlet in the chest.

FUNCTIONS OF THE LYMPHATIC SYSTEM

Here are the most important functions of the lymphatic system:

- **Return of excess filtered fluid.** Normally, capillary filtration exceeds reabsorption by about 3 L per day (20 L filtered, 17 L reabsorbed) (► Figure 9-25b). Yet the entire blood volume is only 5 L, and only 2.75 L of that is plasma. (Blood cells make up the rest of the blood volume.) With an average

cardiac output, 7200 L of blood pass through the capillaries daily under resting conditions (more when cardiac output increases). Even though only a small fraction of the filtered fluid is not reabsorbed by the blood capillaries, the cumulative effect of this process being repeated with every heart-beat results in the equivalent of more than the entire plasma volume left behind in the interstitial fluid each day. Obviously, this fluid must be returned to the circulating plasma, and this task is accomplished by the lymph vessels. The average rate of flow through the lymph vessels is 3 L per day, compared with 7200 L per day through the circulatory system.

- **Defence against disease.** The lymph percolates through **lymph nodes** located en route within the lymphatic system. Passage of this fluid through the lymph nodes is an important aspect of the body’s defence mechanism against disease. For example, bacteria picked up from the interstitial fluid are destroyed by special phagocytes within the lymph nodes (see Chapter 11).

- **Transport of absorbed fat.** The lymphatic system is important in the absorption of fat from the digestive tract. The end products of the digestion of dietary fats are packaged by cells lining the digestive tract into fatty particles that are too large to gain access to the blood capillaries but can easily enter the initial lymphatics (see Chapter 15).

- **Return of filtered protein.** Most capillaries permit leakage of some plasma proteins during filtration. These proteins cannot readily be reabsorbed back into the blood capillaries but can easily gain access to the initial lymphatics. If the proteins were allowed to accumulate in the interstitial fluid rather than being returned to the circulation via the lymphatics, the interstitial fluid–colloid osmotic pressure (an outward pressure) would progressively increase while the plasma–colloid osmotic pressure (an inward pressure) would progressively fall. As a result, filtration forces would gradually increase and reabsorption forces would gradually decrease, resulting in progressive accumulation of fluid in the interstitial spaces at the expense of loss of plasma volume.

► **FIGURE 9-25 Lymphatic system.** (a) Lymph empties into the venous system near its entrance to the right atrium. (b) Lymph flow averages 3 L per day, whereas blood flow averages 7200 L per day.

Oedema and interstitial fluid accumulation

Occasionally, excessive interstitial fluid does accumulate when one of the physical forces acting across the capillary walls becomes abnormal for some reason. Swelling of the tissues because of excess interstitial fluid is known as **oedema**. The causes of oedema can be grouped into four general categories:

1. *A reduced concentration of plasma proteins* decreases plasma-colloid osmotic pressure. Such a drop in the major inward pressure lets excess fluid filter out, whereas less-than-normal amounts of fluid are reabsorbed; hence, extra fluid remains in the interstitial spaces. Oedema can be caused by a decreased concentration of plasma proteins in several different ways: excessive loss of plasma proteins in the urine, from kidney disease; reduced synthesis of plasma proteins, from liver disease (the liver synthesizes almost all plasma proteins); a diet deficient in protein; or significant loss of plasma proteins from large burned surfaces.
2. *Increased permeability of the capillary walls* allows more plasma proteins than usual to pass from the plasma into the surrounding interstitial fluid—for example, via histamine-induced widening of the capillary pores during tissue injury or allergic reactions. The resultant fall in plasma-colloid osmotic pressure decreases the effective inward pressure, whereas the resultant rise in interstitial fluid-colloid osmotic pressure caused by excess protein in the interstitial fluid increases the effective outward force. This imbalance contributes in part to the localized oedema associated with injuries (e.g., blisters) and allergic responses (e.g., hives).
3. *Increased venous pressure*, as when blood dams up in the veins, is accompanied by an increased capillary blood pressure, because the capillaries drain into the veins. This elevation in outward pressure across the capillary walls is largely responsible for the oedema seen with congestive heart failure (p. 371). Regional oedema can also occur because of localized restriction of venous return. An example is the swelling that often occurs in the legs and feet during pregnancy. The enlarged uterus compresses the major veins that drain the lower extremities as these vessels enter the abdominal cavity. The resultant damming of blood in these veins raises blood pressure in the capillaries of the legs and feet, which promotes regional oedema of the lower extremities.
4. *Blockage of lymph vessels* produces oedema because the excess filtered fluid is retained in the interstitial fluid rather than returned to the blood through the lymphatics. Protein accumulation in the interstitial fluid compounds the problem through its osmotic effect. Local lymph blockage can occur, for example, in the arms of women whose major lymphatic drainage channels from the arm have been blocked as a result of lymph node removal during surgery for breast cancer. More widespread lymph blockage occurs with *filariasis*, a mosquito-borne parasitic

© Fred Marsik/Visuals Unlimited

FIGURE 9-26 Elephantiasis. This tropical condition is caused by a mosquito-borne parasitic worm that invades the lymph vessels. As a result of the interference with lymph drainage, the affected body parts, usually the extremities, become grossly oedematous, appearing elephant-like.

disease found predominantly in tropical coastal regions. In this condition, small, threadlike filaria worms infect the lymph vessels, where their presence prevents proper lymph drainage. The affected body parts, particularly the scrotum and extremities, become grossly oedematous. The condition is often called *elephantiasis* because of the elephant-like appearance of the swollen extremities (Figure 9-26).

D.C. McKenzie and colleagues at the University of British Columbia studied the relationship between breast cancer, the lymphatic system, and exercise. The lymphatic system has not been found to limit exercise performance in a healthy population, but the function of the lymphatic system can be impaired in a large percentage of women (about 35%) who have survived breast cancer. The chief role of the lymphatic system during exercise is to help regulate tissue pressure and volume via the movement of fluid and plasma proteins from the interstitial space back into the cardiovascular system. Breast cancer-related lymphoedema (i.e., lymphatic obstruction) results in a chronic swelling, which typically occurs in the ipsilateral arm of those treated for breast cancer. Exercise was initially thought to facilitate the development of breast cancer-related lymphoedema through damage to the axillary lymphatic from breast cancer treatment, but the current view is that the cause is multifactorial and not simply a lymphatic obstruction.

Whatever the cause of oedema, an important consequence is reduced exchange of materials between the blood and cells. As excess interstitial fluid accumulates, the distance between the blood and cells across which nutrients, oxygen, and wastes must diffuse increases, so the rate of diffusion decreases. Therefore, cells within oedematous tissues may not be adequately supplied.

9.5 | Veins

The venous system completes the circulatory circuit. Blood leaving the capillary beds enters the venous system for transport back to the heart.

Venules

At the microcirculatory level, capillaries drain into *venules*, which progressively converge to form small veins that exit the organ. In contrast to arterioles, venules have little tone and resistance. Extensive communication takes place via chemical signals between venules and nearby arterioles. This venuloarteriolar signalling is vital to matching capillary inflow and outflow within an organ.

Veins: A blood reservoir

Veins have a large radius, so they offer little resistance to flow. Furthermore, because the total cross-sectional area of the venous system gradually decreases as smaller veins converge into progressively fewer but larger vessels, blood flow speeds up as blood approaches the heart.

In addition to serving as low-resistance passageways to return blood from the tissues to the heart, systemic veins also serve as a *blood reservoir*. Because of their storage capacity, veins are often called **capacitance vessels**. Veins have much thinner walls with less smooth muscle than arteries have. Also, in contrast to arteries, veins have very little elasticity, because venous connective tissue contains considerably more collagen fibres than elastin fibres. Unlike arteriolar smooth muscle, venous smooth muscle has little inherent myogenic tone. Because of these features, veins are highly distensible, or stretchable, and have little elastic recoil. They easily distend to accommodate additional volumes of blood, even with only a small increase in venous pressure. Arteries stretched by an excess volume of blood recoil because of the elastic fibres in their walls, driving the blood forward. Veins containing an extra volume of blood simply stretch to accommodate the additional blood without tending to recoil. In this way, veins serve as a **blood reservoir**; that is, when demands for blood are low, the veins can store extra blood in reserve because of their passive distensibility. Under resting conditions, the veins contain more than 60 percent of the total blood volume (► Figure 9-27).

Let's clarify a possible point of confusion. Contrary to a common misconception, blood stored in the veins is not being held in a stagnant holding tank. Normally all the blood is circulating all the time. When the body is at rest and many of the capillary beds are closed, the capacity of the venous reservoir is increased as extra blood bypasses the capillaries and enters the veins. When this extra volume of blood stretches the veins, the blood moves forward through the veins more slowly because the total cross-sectional area of the veins has been increased as a result of the stretching. Therefore, the blood spends more time in the veins. As a result of this slower transit time through the veins, the veins are essentially storing the extra volume of blood because it is not moving forward as quickly to the heart to be pumped out again.

► FIGURE 9-27 Percentage of total blood volume in different parts of the circulatory system

When the stored blood is needed, such as during exercise, extrinsic factors (soon to be described) reduce the capacity of the venous reservoir and drive the extra blood from the veins to the heart so it can be pumped to the tissues. Increased venous return leads to an increased cardiac stroke volume, in accordance with the Frank-Starling law of the heart (p. 368). In contrast, if too much blood pools in the veins instead of being returned to the heart, cardiac output is abnormally diminished. In this way, a delicate balance exists between the capacity of the veins, the extent of venous return, and the cardiac output. We now turn our attention to the factors that affect venous capacity and contribute to venous return.

Venous return

Venous capacity, the volume of blood that the veins can accommodate, depends on both the distensibility of the vein walls and the influence of any externally applied pressure that squeezes inwardly on the veins. At a constant blood volume, as venous capacity increases, more blood remains in the veins instead of being returned to the heart. Such venous storage decreases the effective circulating blood volume—that is, the volume of blood returned to and pumped out of the heart. Conversely, when venous capacity decreases, more blood returns to the heart and is subsequently pumped out. Thus, changes in venous capacity directly influence the magnitude of venous return, which in turn is an important (although not the only) determinant of effective circulating blood volume. The effective circulating blood volume is also influenced on a short-term basis by passive shifts in bulk flow between the vascular and interstitial fluid compartments and on a long-term basis by factors that control total ECF volume, such as salt and water balance.

In Chapter 8, we discussed the role of the heart as a pump and all the factors that influence the pump to regulate cardiac output. However, what was missing from that discussion was the influence of the venous side of the circulatory system on cardiac function. The blood that returns to the heart, or **venous return**,

also plays a key role in determining cardiac output. The following discussion outlines the importance of venous return.

The term *venous return* refers to the volume of blood entering each atrium per minute from the veins. Recalling that the circulatory system is a closed loop, it is correct to state that under steady-state conditions, venous return must be equal to cardiac output and that any imbalance of this relationship causes blood to accumulate in either the pulmonary or systemic circulations. An example of an imbalance is what is observed during heart failure (p. 371) or any other disease that increases right atrial pressure.

The venous system is characterized as the low pressure, high capacitance part of the circulation. By the time the blood enters the venous system, blood pressure averages only 17 mmHg (see ▶ Figure 9-9). However, because atrial pressure is near 0 mmHg, a small but adequate driving pressure still exists to promote the flow of blood through the large-radius, low-resistance veins. The other determining factor of venous return is venous capacitance. Unlike the elastic properties of arteries, increasing the volume of blood in the veins does not necessarily lead to a significant rise in pressure. Instead, increasing the volume of blood stored in the veins leads to a decrease in the amount of blood returned to the right atrium and, thus, the right ventricle. According to the Frank–Starling relationship, this reduction in end-diastolic volume (EDV) leads to a decreased cardiac output (see ▶ Figure 8-20). The opposite is also true if the ability of the veins to store blood decreases. Decreased venous capacitance causes more blood to be sent back to the heart, which causes an increase in EDV and, therefore, increases cardiac output.

In addition to the driving pressure imparted by cardiac contraction, there are five main factors that enhance venous return: (1) sympathetically induced venous vasoconstriction, (2) skeletal muscle activity, (3) effect of venous valves, (4) respiratory activity, and (5) effect of cardiac suction (▶ Figure 9-28). Most of these secondary factors affect venous return by influencing the pressure gradient between the veins and the heart. We will examine each in turn.

EFFECT OF SYMPATHETIC ACTIVITY ON VENOUS RETURN

Veins are not very muscular and have little inherent tone, but venous smooth muscle is abundantly supplied with sympathetic nerve fibres. Sympathetic stimulation produces venous vasoconstriction, which modestly elevates venous pressure; this, in turn, increases the pressure gradient to drive more of the stored blood from the veins into the right atrium, thereby enhancing venous return. Veins normally have such a large radius that the moderate vasoconstriction from sympathetic stimulation has little effect on resistance to flow. Even when constricted, veins still have a relatively large radius and are still low-resistance vessels.

In addition to mobilizing the stored blood, venous vasoconstriction enhances venous return by decreasing venous capacity. With the filling capacity of the veins reduced, less of the blood

▶ FIGURE 9-28 Factors that facilitate venous return

draining from the capillaries remains in the veins; instead, it continues to flow toward the heart. The increased venous return initiated by sympathetic stimulation leads to increased cardiac output because end-diastolic volume has increased. Sympathetic stimulation of the heart also increases cardiac output by increasing the heart rate and increasing the heart's contractility (pp. 367 and 369). As long as sympathetic activity remains elevated, as during exercise, the increased cardiac output, in turn, helps sustain the increased venous return initiated in the first place by sympathetically induced venous vasoconstriction. More blood being pumped out by the heart means greater return of blood to the heart, because the reduced-capacity veins do not stretch to store any of the extra blood being pumped into the vascular system.

It is important to recognize the different outcomes of vasoconstriction in arterioles and veins. Arteriolar vasoconstriction immediately *reduces* flow through these vessels because of their increased resistance (less blood can enter and flow through a narrowed arteriole), whereas venous vasoconstriction immediately *increases* flow through these vessels because of their decreased capacity (narrowing of veins squeezes out more of the blood already in the veins, increasing blood flow through these vessels).

EFFECT OF SKELETAL MUSCLE ACTIVITY ON VENOUS RETURN

Many of the large veins in the extremities lie between skeletal muscles, so muscle contraction compresses the veins. This external venous compression decreases venous capacity and increases venous pressure, in effect squeezing fluid in the veins forward toward the heart (► Figure 9-29). This pumping action, known as the **skeletal muscle pump**, is one way that extra blood stored in the veins returns to the heart during exercise. Increased muscular activity pushes more blood out of the veins and into the heart.

The skeletal muscle pump also counters the effect of gravity on the venous system. Let's see how.

COUNTERING THE EFFECTS OF GRAVITY ON THE VENOUS SYSTEM

The average pressures mentioned thus far for various regions of the vascular tree are for a person in the horizontal position. When a person is lying down, the force of gravity is uniformly applied, so it need not be considered. When a person stands up, however, gravitational effects are not uniform. In addition to the usual pressure from cardiac contraction, vessels below heart level are subject to pressure from the weight of the column of blood extending from the heart to the level of the vessel (► Figure 9-30).

There are two important consequences of this increased pressure. First, the distensible veins yield under the increased hydrostatic pressure; they further expand and thereby increase their capacity. Even though the arteries are subject to the same gravitational effects, they are not nearly as distensible and do not expand like the veins. Much of the blood entering from the capillaries tends to pool in the expanded lower leg veins instead of returning to the heart. Because venous return is reduced, cardiac output decreases, and the effective circulating volume

© 2016 Cengage

► FIGURE 9-29 Skeletal muscle pump enhancing venous return

shrinks. Second, the marked increase in capillary blood pressure resulting from the effect of gravity causes excessive fluid to filter out of capillary beds in the lower extremities, producing localized oedema (i.e., swollen feet and ankles).

Two compensatory measures normally counteract these gravitational effects. First, the resultant fall in mean arterial pressure that occurs when a person moves from a lying-down to an upright position triggers sympathetically induced venous vasoconstriction, which drives some of the pooled blood forward. Second, the skeletal muscle pump “interrupts” the column of blood by completely emptying certain vein segments intermittently so that a particular portion of a vein is not subjected to the weight of the entire venous column from the heart to that portion’s level (► Figure 9-29, and ► Figure 9-31). Reflex venous

90 mmHg caused by gravitational effect
10 mmHg caused by pressure imparted by cardiac contraction

FIGURE 9-30 Effect of gravity on venous pressure. In an upright adult, the blood in the vessels extending between the heart and foot is equivalent to a 1.5 m column of blood. The pressure exerted by this column of blood as a result of the effect of gravity is 90 mmHg. The pressure imparted to the blood by the heart declines to about 10 mmHg in the lower leg veins because of frictional losses in preceding vessels. Together these pressures produce a venous pressure of 100 mmHg in the ankle and foot veins. Similarly, the capillaries in the region are subjected to these same gravitational effects.

vasoconstriction cannot completely compensate for gravitational effects without skeletal muscle activity. When a person stands still for a long time, therefore, blood flow to the brain is reduced because of the decline in effective circulating volume, despite

FIGURE 9-31 Effect of contraction of the skeletal muscles of the legs in counteracting the effects of gravity. Contraction of skeletal muscles (as in walking) completely empties given vein segments, interrupting the column of blood that the lower veins must support.

reflexes aimed at maintaining mean arterial pressure. Reduced flow of blood to the brain, in turn, leads to fainting, which returns the person to a horizontal position, eliminating the gravitational effects on the vascular system and restoring effective circulation. For this reason, it is counterproductive to try to hold upright someone who has fainted. Fainting is a remedy to the problem, not the problem itself.

Because the skeletal muscle pump facilitates venous return and helps counteract the detrimental effects of gravity on the circulatory system, when you are working at a desk, it's a good idea to get up periodically, and when you are on your feet, to move around. The mild muscular activity "gets the blood moving." It is further recommended that people who must be on their feet for long periods of time use elastic stockings that apply a continuous gentle external compression, similar to the effect of skeletal muscle contraction, to further counter the effect of gravitational pooling of blood in the leg veins.

EFFECT OF VENOUS VALVES ON VENOUS RETURN

Venous vasoconstriction and external venous compression both drive blood toward the heart. Yet if you squeeze a fluid-filled tube in the middle, fluid is pushed in both directions from the point of constriction (Figure 9-32a). So why isn't blood driven backward as well as forward by venous vasoconstriction and the skeletal muscle pump? Blood can only be driven forward because the large veins are equipped with one-way valves spaced at 2 to 4 cm intervals; these valves let blood move forward toward the heart but keep it from moving back toward the tissues

► **FIGURE 9-32 Function of venous valves.** (a) When a tube is squeezed in the middle, fluid is pushed in both directions. (b) Venous valves permit the flow of blood only toward the heart.

(► Figure 9-32b). These venous valves also play a role in counteracting the gravitational effects of upright posture by helping minimize the backflow of blood that tends to occur when a person stands up and by temporarily supporting portions of the column of blood when the skeletal muscles are relaxed.

Varicose veins occur when the venous valves become incompetent and can no longer support the column of blood above them. People predisposed to this condition usually have inherited an overdistensibility and weakness of their vein walls. Aggravated by frequent, prolonged standing, the veins become so distended as blood pools in them that the edges of the valves can no longer meet to form a seal. Varicose superficial leg veins become visibly overdistended and tortuous. Contrary to what might be expected, chronic pooling of blood in the pathologically distended veins does not reduce cardiac

output, because there is a compensatory increase in total circulating blood volume. Instead, the most serious consequence of varicose veins is the possibility of abnormal clot formation in the sluggish, pooled blood. Particularly dangerous is the risk that these clots may break loose and block small vessels elsewhere, especially the pulmonary capillaries.

EFFECT OF RESPIRATORY ACTIVITY ON VENOUS RETURN

As a result of respiratory activity, the pressure within the chest cavity averages 5 mmHg less than atmospheric pressure. As the venous system returns blood to the heart from the lower regions of the body, it travels through the chest cavity, where it is exposed to this subatmospheric pressure. Because the venous system in the limbs and abdomen is subject to normal atmospheric pressure, an externally applied pressure gradient exists between the lower veins (at atmospheric pressure) and the chest veins (at 5 mmHg less than atmospheric pressure). This pressure difference squeezes blood from the lower veins to the chest veins, promoting increased venous return (► Figure 9-33). This mechanism of facilitating venous return is called the **respiratory pump**, because it results from respiratory activity. Increased respiratory activity and the effects of the skeletal muscle pump and venous vasoconstriction all enhance venous return during exercise.

EFFECT OF CARDIAC SUCTION ON VENOUS RETURN

The extent of cardiac filling does not depend entirely on factors affecting the veins. The heart plays a role in its own filling. During ventricular contraction, the AV valves are drawn downward, enlarging the atrial cavities. As a result, the atrial pressure transiently drops below 0 mmHg, thus increasing the vein-to-atria pressure gradient so that venous return is enhanced. In addition, the rapid expansion of the ventricular chambers during ventricular relaxation creates a transient negative pressure in the ventricles so that blood is sucked in from the atria and veins; that is, the negative ventricular pressure increases the vein-to-atria-to-ventricle pressure gradient, further enhancing venous return. Thus, the heart functions like a suction pump to facilitate cardiac filling.

► **FIGURE 9-33 Respiratory pump enhancing venous return.** As a result of respiratory activity, the pressure surrounding the chest veins is lower than the pressure surrounding the veins in the extremities and abdomen. This establishes an externally applied pressure gradient on the veins, which drives blood toward the heart.

9.6 | Blood Pressure

The blood pressure that is monitored and regulated in the body is the mean arterial pressure. It is not the arterial systolic or diastolic or pulse pressure, nor the pressure in any other part of the vascular tree. Routine blood pressure measurements record the arterial systolic and diastolic pressures, which can be used as a yardstick for assessing mean arterial pressure. The cut-off for normal blood pressure has recently been designated by the American National Institutes of Health (NIH) as being less than 120/80 mmHg (Appendix G lists reference values), and it is recommended under the 2016 Canadian Hypertension Education Program that patients be managed to maintain blood pressure below 140/90 mmHg (<http://www.hypertension.ca>).

Blood pressure regulation

Mean arterial pressure is the main driving force for propelling blood to the tissues. This pressure must be closely regulated for two reasons. First, it must be high enough to ensure sufficient driving pressure; without this pressure, the brain and other organs do not receive adequate flow, no matter what local adjustments are made in the resistance of the arterioles supplying them. Second, the pressure must not be so high that it creates extra work for the heart and increases the risk of vascular damage and possible rupture of small blood vessels.

DETERMINANTS OF MEAN ARTERIAL PRESSURE

Elaborate mechanisms involving the integrated action of the various components of the circulatory system and other body systems are vital in regulating this all-important mean arterial pressure (► Figure 9-34). Remember that the two determinants of mean arterial pressure are cardiac output and total peripheral resistance:

$$\text{Mean arterial pressure} = \frac{\text{cardiac output} \times \text{total peripheral resistance}}{\text{resistance}}$$

(Do not confuse this equation, which indicates the *determinants* of mean arterial pressure, namely, the magnitude of both the cardiac output and total peripheral resistance, with the equation used to *calculate* mean arterial pressure, namely, mean arterial pressure = diastolic pressure + $1/3$ pulse pressure.)

Recall that a number of factors determine cardiac output (see ► Figure 8-23) and total peripheral resistance (see ► Figure 9-14). You can quickly appreciate the complexity of blood pressure regulation. Let's work through ► Figure 9-34, reviewing all the factors that affect mean arterial pressure. Even though we covered all these factors earlier, it is useful to pull them all together. The circled numbers in the text correspond to the numbers in the figure.

- Mean arterial pressure depends on cardiac output and total peripheral resistance (1 in ► Figure 9-34).
- Cardiac output depends on heart rate and stroke volume (2).
- Heart rate depends on the relative balance of parasympathetic activity (3), which decreases heart rate, and sympathetic activity (tacitly including epinephrine throughout this discussion) (4), which increases heart rate.

- Stroke volume increases in response to sympathetic activity (5 (extrinsic control of stroke volume).
- Stroke volume also increases as venous return increases (6 (intrinsic control of stroke volume according to the Frank-Starling law of the heart).
- Venous return is enhanced by sympathetically induced venous vasoconstriction (7), the skeletal muscle pump (8), the respiratory pump (9), and cardiac suction (10).
- The effective circulating blood volume also influences how much blood is returned to the heart (11). The blood volume depends in the short term on the size of passive bulk-flow fluid shifts between plasma and interstitial fluid across the capillary walls (12). In the long term, the blood volume depends on salt and water balance (13), which are hormonally controlled by the renin-angiotensin-aldosterone system and vasopressin, respectively (14).
- The other major determinant of mean arterial blood pressure—total peripheral resistance—depends on the radius of all arterioles as well as blood viscosity (15). The main factor determining blood viscosity is the number of red blood cells (16). However, arteriolar radius is the more important factor determining total peripheral resistance.
- Arteriolar radius is influenced by local (intrinsic) metabolic controls that match blood flow with metabolic needs (17). For example, local changes that take place in active skeletal muscles cause local arteriolar vasodilation and increased blood flow to these muscle (18).
- Arteriolar radius is also influenced by sympathetic activity (19), an extrinsic control mechanism that causes arteriolar vasoconstriction (20) to increase total peripheral resistance and mean arterial blood pressure.
- Arteriolar radius is also extrinsically controlled by the hormones vasopressin and angiotensin II, which are potent vasoconstrictors (21) as well as being important in salt and water balance (22).

Altering any of the pertinent factors that influence blood pressure will change blood pressure, unless a compensatory change in another variable keeps the blood pressure constant. Blood flow to any given organ depends on the driving force of the mean arterial pressure and on the degree of vasoconstriction of the organ's arterioles. Because mean arterial pressure depends on the cardiac output and the degree of arteriolar vasoconstriction, if the arterioles in one organ dilate, the arterioles in other organs must constrict to maintain an adequate arterial blood pressure. An adequate pressure is needed to provide a driving force to push blood not only to the vasodilated organ but also to the brain, which depends on a constant blood supply. Therefore, the cardiovascular variables must be continuously juggled to maintain a constant blood pressure, despite organs' varying needs for blood.

SHORT-TERM AND LONG-TERM CONTROL MEASURES

Mean arterial pressure is constantly monitored by **baroreceptors** (pressure sensors) within the circulatory system. When deviations from normal are detected, multiple reflex responses are initiated to return mean arterial pressure to its normal

© 2016 Cengage

FIGURE 9-34 Determinants of mean arterial blood pressure. Note that this figure is basically a composite of [Figure 8-23](#), Control of cardiac output; [Figure 9-14](#), Factors affecting total peripheral resistance; and [Figure 9-28](#), Factors that facilitate venous return. See the text for a discussion of the circled numbers.

value. *Short-term* (within seconds) adjustments are made by alterations in cardiac output and total peripheral resistance, mediated by means of autonomic nervous system influences on the heart, veins, and arterioles. *Long-term* (requiring minutes to days) control involves adjusting total blood volume by restoring normal salt and water balance through mechanisms that regulate urine output and thirst (Chapters 13 and 14). The size of the total blood volume, in turn, has a profound effect on cardiac output and mean arterial pressure. Let's now examine the short-term mechanisms involved in ongoing regulation of this pressure.

The baroreceptor reflex

Any change in mean arterial pressure triggers an autonomic system-mediated **baroreceptor reflex**, which influences the heart and blood vessels to adjust cardiac output and total peripheral resistance in an attempt to restore blood pressure to normal. Like any reflex, the baroreceptor reflex includes a receptor, an afferent pathway, an integrating centre, an efferent pathway, and effector organs.

The most important receptors involved in the moment-to-moment regulation of blood pressure, the **carotid sinus** and **aortic arch baroreceptors**, are mechanoreceptors sensitive to changes in both mean arterial pressure and pulse pressure. Their responsiveness to fluctuations in pulse pressure enhances their sensitivity as pressure sensors, because small changes in systolic or diastolic pressure may alter the pulse pressure without changing the mean pressure. These baroreceptors are strategically located ([Figure 9-35](#)) to provide critical information about arterial blood pressure in the vessels leading to the brain (the carotid sinus baroreceptor) and in the major arterial trunk before it branches to supply the rest of the body (the aortic arch baroreceptor).

The baroreceptors constantly provide information about mean arterial pressure; in other words, they continuously generate action potentials in response to the ongoing pressure within the arteries. When arterial pressure (either mean or pulse pressure) increases, the receptor potential of these baroreceptors increases, thus increasing the rate of firing in the corresponding afferent neurons. Conversely, a decrease in the mean arterial pressure slows the rate of firing generated in the afferent neurons by the baroreceptors ([Figure 9-36](#)).

► **FIGURE 9-35** Location of the arterial baroreceptors. The arterial baroreceptors are strategically located to monitor the mean arterial blood pressure in the arteries that supply blood to the brain (carotid sinus baroreceptor) and to the rest of the body (aortic arch baroreceptor).

The integrating centre that receives the afferent impulses about the state of mean arterial pressure is the *cardiovascular control centre*, located in the medulla within the brain stem. The efferent pathway is the autonomic nervous system. The cardiovascular control centre alters the ratio between sympathetic and parasympathetic activity to the effector organs (the heart and blood vessels). The cardiovascular control centre is sometimes divided into cardiac and vasomotor centres, which are occasionally further classified into smaller subdivisions, such as cardio-acceleratory and cardioinhibitory centres and vasoconstrictor

and vasodilator areas. Because these regions are highly interconnected and functionally interrelated, we refer to them collectively as the *cardiovascular control centre*.

To review how autonomic changes alter arterial blood pressure, study ► Figure 9-37, which summarizes the major effects of parasympathetic and sympathetic stimulation on the heart and blood vessels.

To fit all the pieces of the baroreceptor reflex together, let's trace the reflex activity that compensates for an elevation or fall in blood pressure. If for any reason mean arterial pressure rises above normal (► Figure 9-38a), the carotid sinus and aortic arch baroreceptors increase the rate of firing in their respective afferent neurons. On being informed by increased afferent firing that the blood pressure has become too high, the cardiovascular control centre responds by decreasing sympathetic and increasing parasympathetic activity to the cardiovascular system. These efferent signals decrease heart rate, decrease stroke volume, and produce arteriolar and venous vasodilation, which in turn lead to a decrease in cardiac output and a decrease in total peripheral resistance, with a subsequent fall in blood pressure back toward normal.

Conversely, when blood pressure falls below normal (► Figure 9-38b), baroreceptor activity decreases, inducing the cardiovascular centre to increase sympathetic cardiac and vasoconstrictor nerve activity while decreasing its parasympathetic output. This efferent pattern of activity leads to an increase in heart rate and stroke volume, coupled with arteriolar and venous vasoconstriction. These changes increase both cardiac output and total peripheral resistance, raising blood pressure back toward normal.

Other reflexes and responses

Besides the baroreceptor reflex, whose sole function is blood pressure regulation, several other reflexes and responses influence the cardiovascular system even though they primarily regulate other body functions. Some of these other influences deliberately move arterial pressure away from its normal value temporarily, overriding the baroreceptor reflex to accomplish a particular goal. These factors include the following:

1. Left atrial volume receptors and hypothalamic osmoreceptors are primarily important in water and salt balance in the body; they affect the long-term regulation of blood pressure by controlling the plasma volume.
2. Chemoreceptors located in the carotid and aortic arteries, in close association with but distinct from the baroreceptors, are sensitive to low oxygen or

► **FIGURE 9-36** Firing rate in an afferent neuron from the carotid sinus baroreceptor in relation to the magnitude of mean arterial pressure

FIGURE 9-37 Summary of the effects of the parasympathetic and sympathetic nervous systems on factors that influence mean arterial blood pressure

(a) Baroreceptor reflex in response to an elevation in blood pressure

(b) Baroreceptor reflex in response to a fall in blood pressure

FIGURE 9-38 Baroreceptor reflexes to restore blood pressure to normal

high acid levels in the blood. These chemoreceptors' main function is to increase respiratory activity to bring in more oxygen or to blow off more acid-forming carbon dioxide, but they also increase blood pressure by sending excitatory impulses to the cardiovascular centre.

- Cardiovascular responses associated with certain behaviours and emotions are mediated through the cerebral cortex–hypothalamic pathway and appear pre-programmed. These responses include the widespread changes in cardiovascular activity that accompany the generalized sympathetic fight-or-flight response, the characteristic marked increase in heart rate and blood pressure associated with sexual orgasm, and the localized cutaneous vasodilation characteristic of blushing.
- Pronounced cardiovascular changes accompany exercise, including a substantial increase in skeletal muscle blood flow (see ▶ Figure 9-12), a significant increase in cardiac output, a fall in total peripheral resistance (because of widespread vasodilation in skeletal muscles despite generalized arteriolar vasoconstriction in most organs), and a modest increase in mean arterial pressure (▶ Table 9-5). Evidence suggests that discrete exercise centres yet to be identified in the brain induce the appropriate cardiac

and vascular changes at the onset of exercise or even in anticipation of exercise. These effects are then reinforced by afferent inputs to the medullary cardiovascular centre from chemoreceptors in exercising muscles as well as by local mechanisms important in maintaining vasodilation in active muscles. The baroreceptor reflex further modulates these cardiovascular responses.

- Hypothalamic control over cutaneous (skin) arterioles for the purpose of temperature regulation takes precedence over control that the cardiovascular centre has over these same vessels for the purpose of blood pressure regulation. As a result, blood pressure can fall when the skin vessels are widely dilated to eliminate excess heat from the body, even though the baroreceptor responses are calling for cutaneous vasoconstriction to help maintain adequate total peripheral resistance.
- Vasoactive substances released from the endothelial cells play a role in regulating blood pressure. For example, nitric oxide normally exerts an ongoing vasodilatory effect.

Despite these control measures, sometimes blood pressure is not maintained at the appropriate level. We next examine blood pressure abnormalities.

■ **TABLE 9-5** Cardiovascular Changes during Exercise

Cardiovascular Variable	Change	Comment
Heart Rate	Increases	Occurs as a result of an increased sympathetic and a decreased parasympathetic activity to the SA node
Venous Return	Increases	Occurs as a result of sympathetically induced venous vasoconstriction and increased activity of the skeletal muscle pump and respiratory pump
Stroke Volume	Increases	Occurs both as a result of increased venous return by means of the Frank–Starling mechanism (unless diastolic filling time is significantly reduced by a high heart rate) and as a result of a sympathetically induced increase in myocardial contractility
Cardiac Output	Increases	Occurs as a result of increases in both heart rate and stroke volume
Blood Flow to Active Skeletal Muscles and Heart Muscle	Increases	Occurs as a result of locally controlled arteriolar vasodilation, which is reinforced by the vasodilatory effects of epinephrine and overpowers the weaker sympathetic vasoconstrictor effect
Blood Flow to the Brain	Unchanged	Occurs because sympathetic stimulation has no effect on brain arterioles; local control mechanisms maintain constant cerebral blood flow, whatever the circumstances
Blood Flow to the Skin	Increases	Occurs because the hypothalamic temperature control centre induces vasodilation of skin arterioles; increased skin blood flow brings heat produced by exercising muscles to the body surface where the heat can be lost to the external environment
Blood Flow to the Digestive System, Kidneys, and Other Organs	Decreases	Occurs as a result of generalized sympathetically induced arteriolar vasoconstriction
Total Peripheral Resistance	Decreases	Occurs because resistance in the skeletal muscles, heart, and skin decreases to a greater extent than resistance in the other organs increases
Mean Arterial Blood Pressure	Increases (modest)	Occurs because cardiac output increases to a greater extent than total peripheral resistance decreases

Hypertension

Sometimes blood pressure control mechanisms do not function properly or are unable to completely compensate for changes that have taken place. Blood pressure may be too high (**hypertension** if above 140/90 mmHg) or too low (**hypotension** if below 100/60 mmHg). Hypotension in its extreme form is called *circulatory shock*. We will first examine hypertension, which is by far the most common of blood pressure abnormalities, and then conclude this chapter with a discussion of hypotension and shock.

There are two broad classes of hypertension: secondary hypertension and primary hypertension, depending on the cause.

SECONDARY HYPERTENSION

A definite cause for hypertension can be established in only 10 percent of cases: specifically, those called **secondary hypertension**, which occurs secondary to another known primary problem. Here are some examples of secondary hypertension:

1. **Renal hypertension.** For example, atherosclerotic lesions protruding into the lumen of a renal artery or external compression of the vessel by a tumour may reduce blood flow through the kidney. The kidney responds by initiating the hormonal pathway involving angiotensin II. This pathway promotes salt and water retention during urine formation, thereby increasing the blood volume to compensate for the reduced renal blood flow. Recall that angiotensin II is also a powerful vasoconstrictor. Although these two effects (increased blood volume and angiotensin-induced vasoconstriction) are compensatory mechanisms to improve blood flow through the narrowed renal artery, they also are responsible for elevating the arterial pressure as a whole.
2. **Endocrine hypertension.** For example, a *pheochromocytoma* is an adrenal medullary tumour that secretes excessive epinephrine and norepinephrine. Abnormally elevated levels of these hormones bring about a high cardiac output and generalized peripheral vasoconstriction, both of which contribute to the hypertension characteristic of this disorder.
3. **Neurogenic hypertension.** An example is the hypertension caused by erroneous blood pressure control arising from a defect in the cardiovascular control centre.

PRIMARY HYPERTENSION

In the remaining 90 percent of hypertension cases the underlying cause is unknown. Such hypertension is known as **primary (essential or idiopathic) hypertension**. Primary hypertension is a catchall category for blood pressure elevated by a variety of unknown causes rather than by a single disease entity. People show a strong genetic tendency to develop primary hypertension, which can be hastened or worsened by contributing factors, such as obesity, stress, smoking, or dietary habits. Consider the following range of potential causes for primary hypertension currently being investigated.

- **Defects in salt management by the kidneys.** Disturbances in kidney function too minor to produce outward signs of renal

disease could nevertheless insidiously lead to gradual accumulation of salt and water in the body, resulting in progressive elevation of arterial pressure.

- **Excessive salt intake.** Because salt osmotically retains water, thus expanding the plasma volume and contributing to the long-term control of blood pressure, excessive ingestion of salt could theoretically contribute to hypertension. Yet controversy continues over whether or not restricting salt intake should be recommended as a means of preventing and treating high blood pressure. The research data to date have been inconclusive and subject to conflicting interpretations.
- **Diets low in fruits, vegetables, and dairy products (i.e., low in K^+ and Ca^{2+}).** Dietary factors other than salt have been shown to markedly affect blood pressure. The DASH (Dietary Approaches to Stop Hypertension) studies found that a low-fat diet rich in fruits, vegetables, and dairy products could lower blood pressure in people with mild hypertension as much as any single drug treatment. Research indicates that the high potassium intake associated with eating abundant fruits and vegetables may lower blood pressure by relaxing arteries. Furthermore, inadequate calcium intake from dairy products has been identified as the most prevalent dietary pattern among individuals with untreated hypertension, although the role of calcium in regulating blood pressure is unclear.
- **Plasma membrane abnormalities, such as defective $Na^+ - K^+$ pumps.** Such defects, by altering the electrochemical gradient across plasma membranes, could change the excitability and contractility of the heart and the smooth muscle in blood vessel walls in such a way as to lead to high blood pressure. In addition, the $Na^+ - K^+$ pump is crucial to salt management by the kidneys. A genetic defect in the $Na^+ - K^+$ pump of hypertensive-prone laboratory rats was the first gene-hypertension link to be discovered.
- **Variation in the gene that encodes for angiotensinogen.** Angiotensinogen is part of the hormonal pathway that produces the potent vasoconstrictor angiotensin II and promotes salt and water retention. One variant of the gene in humans appears to be associated with a higher incidence of hypertension. Researchers speculate that the suspect version of the gene leads to a slight excess production of angiotensinogen, which increases activity of this blood pressure-raising pathway. This is the first gene-hypertension link discovered in humans.
- **Endogenous digitalis-like substances.** Such substances act in much the same way as the drug digitalis (p. 357) to increase cardiac contractility and also to constrict blood vessels and reduce salt elimination in the urine, all of which could cause chronic hypertension.
- **Abnormalities in nitric oxide, endothelin, or other locally acting vasoactive chemicals.** For example, a shortage of nitric oxide has been discovered in the blood vessel walls of some hypertensive patients, leading to an impaired ability to accomplish blood pressure-lowering vasodilation. Furthermore, an underlying abnormality in the gene that codes

for endothelin, a locally acting vasoconstrictor, has been strongly implicated as a possible cause of hypertension, especially among those of African descent.

- *Excess vasopressin.* Recent experimental evidence suggests that hypertension may result from a malfunction of the vasopressin-secreting cells of the hypothalamus. Vasopressin is a potent vasoconstrictor and also promotes water retention.

Whatever the underlying defect, once initiated, hypertension appears to be self-perpetuating. Constant exposure to elevated blood pressure predisposes vessel walls to the development of atherosclerosis, which further raises blood pressure. (But acute, transient rises in blood pressure can be found in some exercise conditions.)

ADAPTATION OF BARORECEPTORS DURING HYPERTENSION

The baroreceptors do not respond to bring the blood pressure back to normal during hypertension because they adapt, or become reset, to operate at a higher level. In the presence of chronically elevated blood pressure, the baroreceptors still function to regulate blood pressure, but they maintain it at a higher mean pressure.

COMPLICATIONS OF HYPERTENSION

Hypertension imposes stresses on both the heart and the blood vessels. The heart has an increased workload because it has to pump against an increased total peripheral resistance, whereas blood vessels may be damaged by the high internal pressure, particularly when the vessel wall is weakened by the degenerative process of atherosclerosis. Complications of hypertension include congestive heart failure caused by the heart's inability to pump continuously against a sustained elevation in arterial pressure, strokes caused by rupture of brain vessels, and heart attacks caused by rupture of coronary vessels. Spontaneous haemorrhage due to the bursting of small vessels elsewhere in the body may also occur, but with less serious consequences; an example is the rupture of blood vessels in the nose, resulting in nosebleeds. Another serious complication of hypertension is renal failure caused by progressive impairment of blood flow through damaged renal blood vessels. Furthermore, retinal damage from changes in the blood vessels supplying the eyes may result in progressive loss of vision.

Until complications occur, hypertension is symptomless, because the tissues are adequately supplied with blood. Therefore, unless blood pressure measurements are made on a routine basis, the condition can go undetected until a precipitous complicating event. When you become aware of these potential complications of hypertension and consider that 22 percent of all adults in Canada are estimated to have chronically elevated blood pressure, you can appreciate the magnitude of this national health problem.

TREATMENT OF HYPERTENSION

Once hypertension is detected, therapeutic intervention can reduce the course and severity of the problem. Dietary management, including weight loss, along with a variety of drugs that

manipulate salt and water management or autonomic activity on the cardiovascular system can be used to treat hypertension. No matter what the original cause, agents that reduce plasma volume or total peripheral resistance (or both) will decrease blood pressure toward normal. Furthermore, a regular aerobic exercise program can be employed to help reduce high blood pressure.

Prehypertension

In its recent guidelines, the U.S. National Institute of Health identified **prehypertension** as a new category for blood pressures in the range between normal and hypertension (between 120/80 and 139/89). Blood pressures in the prehypertension range can usually be reduced by appropriate dietary and exercise measures, whereas those in the hypertension range typically must be treated with blood pressure medication in addition to changing health habits. The goal in managing blood pressures in the prehypertension range is to take action before the pressure climbs into the hypertension range, where serious complications may develop.

Now we look at the other extreme, hypotension: first, transient orthostatic hypotension, and then, the (more serious) circulatory shock.

Orthostatic hypotension

Hypotension, or low blood pressure, occurs either when there is a disproportion between vascular capacity and blood volume (in essence, too little blood to fill the vessels) or when the heart is too weak to drive the blood.

The most common situation in which hypotension occurs transiently is orthostatic hypotension. **Orthostatic (postural) hypotension** is a transient hypotensive condition resulting from insufficient compensatory responses to the gravitational shifts in blood when a person moves from a horizontal to a vertical position, especially after prolonged bed rest. When a person moves from lying down to standing up, pooling of blood in the leg veins from gravity reduces venous return, decreasing stroke volume, and thus lowering cardiac output and blood pressure. This fall in blood pressure is normally detected by the baroreceptors, which initiate immediate compensatory responses to restore blood pressure to its proper level. When a long-bedridden patient first starts to rise, however, these reflex compensatory adjustments are temporarily lost or reduced because of disuse. Sympathetic control of the leg veins is inadequate, so when the patient first stands up, blood pools in the lower extremities. The condition is further aggravated by the decrease in blood volume that typically accompanies prolonged bed rest. The resultant orthostatic hypotension and decrease in blood flow to the brain cause dizziness or actual fainting. Because postural compensatory mechanisms are depressed during prolonged bed confinement, patients sometimes are put on a tilt table so that they can be moved gradually from a horizontal to an upright position. This allows the body to adjust slowly to the gravitational shifts in blood.

Circulatory shock

When blood pressure falls so low that adequate blood flow to the tissues can no longer be maintained, the condition known as **circulatory shock** occurs. Circulatory shock is categorized into four main types (► Figure 9-39):

1. *Hypovolemic* (low-volume) *shock* is caused by a fall in blood volume, which occurs either directly through severe haemorrhage or indirectly through loss of fluids derived from the plasma (e.g., severe diarrhoea, excessive urinary losses, or extensive sweating).
2. *Cardiogenic* (heart-produced) *shock* is due to a weakened heart's failure to pump blood adequately.
3. *Vasogenic* (vessel-produced) *shock* is caused by widespread vasodilation triggered by the presence of vasodilator substances. There are two types of vasogenic shock: septic and anaphylactic. *Septic shock*, which may accompany massive infections, is due to vasodilator substances released from the infective agents. Similarly, extensive histamine release in severe allergic reactions can cause widespread vasodilation in *anaphylactic shock*.
4. *Neurogenic* (nerve-produced) *shock* also involves generalized vasodilation, but not by means of the release of vasodilator substances. In this case, loss of sympathetic

vascular tone leads to generalized vasodilation. This undoubtedly is responsible for the shock accompanying crushing injuries when blood loss has not been sufficient to cause hypovolemic shock. Deep, excruciating pain apparently inhibits sympathetic vasoconstrictor activity.

Using haemorrhage as an example (► Figure 9-40), we now examine the consequences of and compensations for shock. This figure may look intimidating, but we will work through it step by step. It is an important example that pulls together many of the principles discussed in this chapter. As before, the squared numbers in the text correspond to the numbers in the figure.

CONSEQUENCES AND COMPENSATIONS OF SHOCK

- Following severe loss of blood, the resultant reduction in circulating blood volume leads to a decrease in venous return **1** and a subsequent fall in cardiac output and arterial blood pressure. (Note the blue boxes, which indicate consequences of haemorrhage.)
- Compensatory measures immediately attempt to maintain adequate blood flow to the brain. (Note the pink boxes, which indicate compensations for haemorrhage.)
- The baroreceptor reflex response to the fall in blood pressure brings about increased sympathetic and decreased

► **FIGURE 9-39 Causes of circulatory shock.** Circulatory shock, which occurs when mean arterial blood pressure falls so low that adequate blood flow to the tissues can no longer be maintained, may result from (1) extensive loss of blood volume (hypovolemic shock), (2) failure of the heart to pump blood adequately (cardiogenic shock), (3) widespread arteriolar vasodilation (vasogenic shock), or (4) neurally defective vasoconstrictor tone (neurogenic shock).

► **FIGURE 9-40 Consequences and compensations of haemorrhage.** The reduction in blood volume resulting from haemorrhage leads to a fall in arterial pressure. (Note the blue boxes, representing consequences of haemorrhage.) A series of compensations ensue (light pink boxes) that ultimately restore plasma volume, arterial pressure, and the number of red blood cells toward normal (dark pink boxes). Refer to the text for an explanation of the circled numbers and a detailed discussion of the compensations.

parasympathetic activity to the heart **2**. The result is an increase in heart rate **3** to offset the reduced stroke volume **4** brought about by the loss of blood volume. With severe fluid loss, the pulse is weak because of the reduced stroke volume but rapid because of the increased heart rate.

- Increased sympathetic activity to the veins produces generalized venous vasoconstriction **5**, increasing venous return by means of the Frank–Starling mechanism **6**.
- Simultaneously, sympathetic stimulation of the heart increases the heart's contractility **7** so that it beats more forcefully and ejects a greater volume of blood, likewise increasing the stroke volume.
- The increase in heart rate and in stroke volume collectively increase cardiac output **8**.
- Sympathetically induced generalized arteriolar vasoconstriction **9** leads to an increase in total peripheral resistance **10**.
- Together, the increase in cardiac output and total peripheral resistance bring about a compensatory increase in arterial pressure **11**.
- The original fall in arterial pressure is also accompanied by a fall in capillary blood pressure **12**, which results in fluid shifts from the interstitial fluid into the capillaries to expand the plasma volume **13**. This response is sometimes termed *autotransfusion*, because it restores the plasma volume as a transfusion does.
- This ECF shift is enhanced by plasma protein synthesis by the liver during the next few days following haemorrhage **14**. The plasma proteins exert a colloid osmotic pressure that helps retain extra fluid in the plasma.
- Urinary output is reduced, thereby conserving water that normally would have been lost from the body **15**. This additional fluid retention helps expand the reduced plasma volume **16**. Expansion of plasma volume further augments the increase in cardiac output brought about by the baroreceptor reflex **17**. Reduction in urinary output results from decreased renal blood flow caused by compensatory renal arteriolar vasoconstriction **18**. The reduced plasma volume also triggers increased secretion of the hormone vasopressin and activation of the salt- and water-conserving renin–angiotensin–aldosterone hormonal pathway, which further reduces urinary output **19**.
- Increased thirst is also stimulated by a fall in plasma volume **20**. The resultant increased fluid intake helps restore plasma volume.
- Over a longer course of time (a week or more), lost red blood cells are replaced through increased red blood cell production, which is triggered by a reduction in oxygen delivery to the kidneys **21**.

IRREVERSIBLE SHOCK

These compensatory mechanisms are often not enough to counteract substantial fluid loss. Even if they can maintain an adequate blood pressure level, the short-term measures cannot

continue indefinitely. Ultimately, fluid volume must be replaced from the outside through drinking, transfusion, or a combination of both. Blood supply to the kidneys, digestive tract, skin, and other organs can be compromised to maintain blood flow to the brain only so long before organ damage begins to occur. A point may be reached at which blood pressure continues to drop rapidly because of tissue damage, despite vigorous therapy. This condition is frequently termed *irreversible shock*, in contrast to *reversible shock*, which can be corrected by compensatory mechanisms and effective therapy.

Although the exact mechanism underlying irreversibility is not currently known, many logical possibilities could contribute to the unrelenting, progressive circulatory deterioration that characterizes irreversible shock. Metabolic acidosis arises when lactic acid production increases as blood-deprived tissues resort to anaerobic metabolism. Acidosis deranges the enzymatic systems responsible for energy production, and this limits the capability of the heart and other tissues to produce ATP. Prolonged depression of kidney function results in electrolyte imbalances that may lead to cardiac arrhythmias. The blood-deprived pancreas releases a chemical that is toxic to the heart (**myocardial toxic factor**), further weakening the heart. Vasodilator substances build up within ischemic organs, inducing local vasodilation that overrides the generalized reflex vasoconstriction. As cardiac output progressively declines because of the heart's diminishing effectiveness as a pump and total peripheral resistance continues to fall, hypotension becomes increasingly more severe. This causes further cardiovascular failure, which leads to a further decline in blood pressure. Consequently, when shock progresses to the point that the cardiovascular system itself starts to fail, a vicious positive-feedback cycle ensues that ultimately results in death.

Chapter in Perspective: Focus on Homeostasis

Homeostatically, the blood vessels serve as passageways to transport blood to and from the cells for oxygen and nutrient delivery, waste removal, distribution of fluid and electrolytes, elimination of excess heat, and hormonal signalling, among other things. Cells soon die if deprived of their blood supply; brain cells succumb within four minutes. Blood is constantly recycled and reconditioned as it travels through the various organs via the vascular highways. Hence, the body needs only a very small volume of blood to maintain the appropriate chemical composition of the entire internal fluid environment on which the cells depend for their survival. For example, oxygen is continually picked up by blood in the lungs and constantly delivered to all the body cells.

The smallest blood vessels, the capillaries, are the actual site of exchange between the blood and surrounding cells. Capillaries bring homeostatically maintained blood within 0.01 cm of every cell in the body; this proximity is critical, because beyond a few centimetres materials cannot diffuse rapidly enough to support life-sustaining activities. Oxygen that would take months to years to diffuse from the lungs to all the cells of the body is continuously delivered at the

“doorstep” of every cell, where diffusion can efficiently accomplish short local exchanges between the capillaries and surrounding cells. Likewise, hormones must be rapidly transported through the circulatory system from their sites of production in endocrine glands to their sites of action in other parts of the body. These chemical messengers could not diffuse nearly rapidly enough to their target organs to effectively exert their controlling effects, many of which are aimed toward maintaining homeostasis.

The rest of the circulatory system is designed to transport blood to and from the capillaries. The arteries and arterioles distribute blood pumped by the heart to the capillaries for life-sustaining exchanges to take place, and the venules and veins collect blood from the capillaries and return it to the heart, where the process is repeated.

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-44)

- In general, the parallel arrangement of the vascular system enables each organ to receive its own separate arterial blood supply. (*True or false?*)
- More blood flows through the capillaries during cardiac systole than during diastole. (*True or false?*)
- The capillaries contain only 5 percent of the total blood volume at any point in time. (*True or false?*)
- The same volume of blood passes through the capillaries in a minute as passes through the aorta, even though blood flow is much slower in the capillaries. (*True or false?*)
- Because capillary walls have no carrier transport systems, all capillaries are equally permeable. (*True or false?*)
- Because of gravitational effects, venous pressure in the lower extremities is greater when a person is standing up than when the person is lying down. (*True or false?*)
- Which change would increase the resistance in an arteriole?
 - a shorter length
 - a wider calibre
 - increased sympathetic stimulation
 - decreased blood viscosity
- Which of the following functions is (are) attributable to arterioles? (*Indicate all correct answers.*)
 - produce a significant decline in mean pressure, which helps establish the driving pressure gradient between the heart and organs
 - serve as site of exchange of materials between blood and surrounding tissue cells

- c. act as main determinant of total peripheral resistance
- d. determine the pattern of distribution of cardiac output
- e. help regulate mean arterial blood pressure
- f. convert the pulsatile nature of arterial blood pressure into a smooth, nonfluctuating pressure in the vessels farther downstream
- g. act as a pressure reservoir

9. Using the answer code on the right, indicate whether the following factors increase or decrease venous return:

- | | |
|---|------------------------------------|
| _____ 1. sympathetically induced venous vasoconstriction | (a) increases venous return |
| _____ 2. skeletal muscle activity | (b) decreases venous return |
| _____ 3. gravitational effects on the venous system | (c) has no effect on venous return |
| _____ 4. respiratory activity | |
| _____ 5. increased atrial pressure associated with a leaky AV valve | |
| _____ 6. ventricular pressure change associated with diastolic recoil | |

10. Using the answer code on the right, indicate what kind of compensatory changes occur in the factors in question to restore blood pressure to normal in response to hypovolemic hypotension resulting from severe haemorrhage:

- | | |
|---|---------------|
| _____ 1. rate of afferent firing generated by the carotid sinus and aortic arch baroreceptors | (a) increased |
| _____ 2. sympathetic output by the cardiovascular centre | (b) decreased |
| _____ 3. parasympathetic output by the cardiovascular centre | (c) no effect |
| _____ 4. heart rate | |
| _____ 5. stroke volume | |
| _____ 6. cardiac output | |
| _____ 7. arteriolar radius | |
| _____ 8. total peripheral resistance | |
| _____ 9. venous radius | |
| _____ 10. venous return | |
| _____ 11. urinary output | |
| _____ 12. fluid retention within the body | |
| _____ 13. fluid movement from interstitial fluid into plasma across the capillaries | |

Written Questions

- Compare blood flow through reconditioning organs and through organs that do not recondition the blood.
- Discuss the relationships among flow rate, pressure gradient, and vascular resistance. What is the major determinant of resistance to flow?

- Describe the structure and major functions of each segment of the vascular tree.
- How do the arteries serve as a pressure reservoir?
- Describe the indirect technique of measuring arterial blood pressure by means of a sphygmomanometer.
- Define *vasoconstriction* and *vasodilation*.
- Discuss the local and extrinsic controls that regulate arteriolar resistance.
- What is the primary means by which individual solutes are exchanged across capillary walls? What forces produce bulk flow across capillary walls? Of what importance is bulk flow?
- How is lymph formed? What are the functions of the lymphatic system?
- Define *oedema*, and discuss its possible causes.
- How do veins serve as a blood reservoir?
- Compare the effect of vasoconstriction on the rate of blood flow in arterioles and veins.
- Discuss the factors that determine mean arterial pressure.
- Review the effects on the cardiovascular system of parasympathetic and sympathetic stimulation.
- Differentiate between secondary hypertension and primary hypertension. What are the potential consequences of hypertension?
- Define *circulatory shock*. What are its consequences and compensations? What is irreversible shock?

Quantitative Exercises (Solutions in Appendix E, p. A-44)

- Recall that the flow rate of blood equals the pressure gradient divided by the total peripheral resistance of the vascular system. The conventional unit of resistance in physiological systems is expressed in PRU (peripheral resistance unit), which is defined as $(1 \text{ L/min})/(1 \text{ mmHg})$. At rest, Tom's total peripheral resistance is about 20 PRU. Last week while playing racquetball, his cardiac output increased to 30 L/min and his mean arterial pressure increased to 120 mmHg. What was his total peripheral resistance during the game?
- Systolic pressure rises as a person ages. By age 85, an average male has a systolic pressure of 180 mmHg and a diastolic pressure of 90 mmHg.
 - What is the mean arterial pressure of this average 85-year-old male?
 - From your knowledge of capillary dynamics, predict the result at the capillary level of this age-related change in mean arterial pressure if no homeostatic mechanisms were operating. (Recall that mean arterial pressure is about 93 mmHg at age 20.)

3. Compare the flow rates in the systemic and the pulmonary circulations of an individual with the following measurements:

systemic mean arterial pressure = 95 mmHg

systemic resistance = 19 PRU

pulmonary mean arterial pressure = 20 mmHg

pulmonary resistance = 4 PRU

4. Assume a person has a blood pressure recording of 125/77:
- What is the systolic pressure?
 - What is the diastolic pressure?

- What is the pulse pressure?
- What is the mean arterial pressure?
- Would any sound be heard when the pressure in an external cuff around the arm was 130 mmHg? (*Yes or no?*)
- Would any sound be heard when cuff pressure was 118 mmHg?
- Would any sound be heard when cuff pressure was 75 mmHg?

POINTS TO PONDER

(Explanations in Appendix E, p. A-45)

- During coronary bypass surgery, a piece of vein is often removed from the patient's leg and surgically attached within the coronary circulatory system so that blood detours, through the vein, around an occluded coronary artery segment. Why must the patient wear, for an extended period of time after surgery, an elastic support stocking on the limb from which the vein was removed?
- A classmate who has been standing still for several hours working on a laboratory experiment suddenly faints. What is the probable explanation? What would you do if the person next to him tried to get him up?
- A drug applied to a piece of excised arteriole causes the vessel to relax, but an isolated piece of arteriolar muscle stripped from the other layers of the vessel fails to respond to the same drug. What is the probable explanation?

4. Explain how each of the following antihypertensive drugs would lower arterial blood pressure:
- drugs that block α_1 -adrenergic receptors (e.g., *phentolamine*)
 - drugs that block β_1 -adrenergic receptors (e.g., *metoprolol*) (*Hint: Review adrenergic receptors on p. 193.*)
 - drugs that directly relax arteriolar smooth muscle (e.g., *hydralazine*)
 - diuretic drugs that increase urinary output (e.g., *furosemide*)
 - drugs that block release of norepinephrine from sympathetic endings (e.g., *guanethidine*)
 - drugs that act on the brain to reduce sympathetic output (e.g., *clonidine*)
 - drugs that block Ca^{2+} channels (e.g., *verapamil*)
 - drugs that interfere with the production of angiotensin II (e.g., *captopril*)

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-45)

Li-Ying C. has just been diagnosed as having hypertension secondary to a *pheochromocytoma*, a tumour of the adrenal medulla that secretes excessive epinephrine. Explain how this condition

leads to secondary hypertension, by describing the effect that excessive epinephrine would have on various factors that determine arterial blood pressure.

The Blood

Body systems maintain homeostasis

Cardiovascular system

Cells make up body systems

Homeostasis

Blood contributes to homeostasis by serving as the vehicle for transporting materials to and from the cells, buffering changes in pH, carrying excess heat to the body surface for elimination, playing a major role in the body's defence system, and minimizing blood loss when a blood vessel is damaged.

Homeostasis is essential for survival of cells

Dr. Yorgos Nikas/Science Source

Scanning electron micrograph showing red blood cells, a T lymphocyte, and platelets

Blood is the vehicle for long-distance, mass transport of materials between cells and the external environment or between the cells themselves. Such transport is essential for maintaining homeostasis. Blood consists of a complex liquid plasma in which the cellular elements—*erythrocytes*, *leukocytes*, and *platelets*—are suspended. Erythrocytes (red blood cells or RBCs) are essentially plasma membrane-enclosed bags

of haemoglobin that transport oxygen in the blood. Leukocytes (white blood cells or WBCs), the immune system's mobile defence units, are transported in the blood to sites of injury or of invasion by disease-causing microorganisms. Platelets (thrombocytes) are important in haemostasis, specifically, in the stopping of bleeding from an injured vessel.

Clinical Connections

Christine is 55 and has been an avid runner for 20 years. For the past month or so she has been finding her runs harder and harder. It has come to the point that she finds herself struggling to maintain her regular pace for even a 5 km run. While running, she feels her exertion level is much higher because she finds herself more breathless than usual and recovery after the run takes longer. Most days she generally feels tired all day long and goes to bed early. Both her children have grown and no longer living at home, so she finds herself working longer and not necessarily eating balanced meals as well as she used to. Concerned about fatigue, she met with her physician, who ordered standard blood work. The most overt result was a decreased hematocrit. After ruling out the potential for internal haemorrhage, Christine was put on iron supplements. Within a few weeks she was back to normal. Her diagnosis was iron deficiency anemia due to an iron-poor diet.

10.1 | Introduction

Blood represents about 8 percent of total body weight and has an average volume of 5 L in women and 5.5 L in men. It consists of three types of specialized cellular elements, *erythrocytes* (*red blood cells*), *leukocytes* (*white blood cells*), and *platelets* (*thrombocytes*), suspended in the complex liquid *plasma* (■ Table 10-1). Erythrocytes and leukocytes are both whole cells, whereas platelets are cell fragments. For convenience, we refer collectively to all these blood cellular elements as *blood cells*.

■ **TABLE 10-1** Blood Constituents and Their Functions

Constituent	Functions
Plasma	
Water	Transport medium; carries heat
Electrolytes	Membrane excitability; osmotic distribution of fluid between ECF and ICF; buffer pH changes
Nutrients, wastes, gases, hormones	Transported in blood; the blood gas CO ₂ plays a role in acid–base balance
Plasma proteins	In general, exert an osmotic effect important in the distribution of ECF between the vascular and interstitial compartments; buffer pH changes
<i>Albumins</i>	Transport many substances; contribute most to colloid osmotic pressure
<i>Globulins</i>	
Alpha and beta	Transport many water-insoluble substances; clotting factors; inactive precursor molecules
Gamma	Antibodies
<i>Fibrinogen</i>	Inactive precursor for the fibrin meshwork of a clot
Cellular Elements	
Erythrocytes	Transport O ₂ and CO ₂ (mainly O ₂)
Leukocytes	
Neutrophils	Phagocytes that engulf bacteria and debris
Eosinophils	Attack parasitic worms; important in allergic reactions
Basophils	Release histamine, which is important in allergic reactions, and heparin, which helps clear fat from the blood
Monocytes	In transit to become tissue macrophages
Lymphocytes	
B lymphocytes	Produce antibodies
T lymphocytes	Cell-mediated immune responses
Platelets	Haemostasis

© 2016 Cengage

The constant movement of blood as it flows through the blood vessels keeps the blood cells rather evenly dispersed within the plasma. However, if you put a sample of whole blood in a test tube and treat it to prevent clotting, the heavier cells slowly settle to the bottom and the lighter plasma rises to the top. This process can be speeded up by centrifuging, which quickly packs the cells in the bottom of the tube (► Figure 10-1). Because more than 99 percent of the cells are erythrocytes, the **haematocrit**, or **packed cell volume**, essentially represents the percentage of erythrocytes in the total blood volume. The haematocrit averages 42 percent for women and slightly higher, 45 percent, for men. Plasma accounts for the remaining volume. Accordingly, the average volume of plasma in the blood is 58 percent for women and 55 percent for men. White blood cells and platelets, which are colourless and less dense than red cells, are packed in a thin, cream-coloured layer, the *buffy coat*, on top of the packed red cell column. They account for less than 1 percent of the total blood volume.

Let's first consider the properties of the largest portion of the blood, the plasma, before turning our attention to the cellular elements.

10.2 | Plasma

Plasma, being a liquid, consists of 90 percent water.

Plasma water

Plasma water serves as a medium for materials that are carried in the blood. Also, because water has a high capacity to hold heat, plasma can absorb and distribute much of the heat generated metabolically within tissues, whereas the temperature of the blood itself undergoes only small changes. As blood travels close to the surface of the skin, heat energy not needed to maintain body temperature is eliminated to the environment.

A large number of inorganic and organic substances are dissolved in the plasma. Inorganic constituents account for about 1 percent of plasma weight. The most abundant electrolytes (ions) in the plasma are sodium and chloride, the components of common salt. There are smaller amounts of bicarbonate, potassium, calcium, and others. The most notable functions of these ions are their roles in membrane excitability, osmotic

distribution of fluid between the ECF and cells, and buffering of pH changes.

The most plentiful organic constituents by weight are the plasma proteins, which compose 6–8 percent of plasma's total weight. The remaining small percentage of plasma consists of other organic substances, including nutrients (such as glucose, amino acids, lipids, and vitamins), waste products (creatinine, bilirubin, and nitrogenous substances, such as urea), dissolved gases (O_2 and CO_2), and hormones. Most of these substances are merely being transported in the plasma. For example, endocrine glands secrete hormones into the plasma, which transports these chemical messengers to their sites of action.

We now examine the plasma proteins.

Plasma proteins

Plasma proteins are the one group of plasma constituents that are not just along for the ride. These important components normally stay in the plasma, where they perform many valuable functions. Here are the most important of these functions:

1. Unlike other plasma constituents that are dissolved in the plasma water, plasma proteins are dispersed as a colloid (Appendix B, p. A-10). Furthermore, because they are the largest of the plasma constituents, plasma proteins usually do not exit through the narrow pores in the capillary walls to enter the interstitial fluid.

By their presence as a colloidal dispersion in the plasma and their absence in the interstitial fluid, plasma proteins establish an osmotic gradient between blood

and interstitial fluid. This colloid osmotic pressure is the primary force that prevents excessive loss of plasma from the capillaries into the interstitial fluid, which helps maintain plasma volume (p. 409).

2. Plasma proteins are partially responsible for plasma's capacity to buffer changes in pH (p. 625).
3. The three groups of plasma proteins—*albumins*, *globulins*, and *fibrinogen*—are classified according to their various physical and chemical properties (Appendix F lists normal values). In addition to the general functions just listed, each type of plasma protein performs specific tasks, as follows:

- a. **Albumins**, the most abundant plasma proteins, contribute most extensively to the colloid osmotic pressure by virtue of their numbers. They also nonspecifically bind many substances that are poorly soluble in plasma (such as bilirubin, bile salts, and penicillin) for transport in the plasma.

- b. There are three subclasses of globulins: **alpha (α) globulins**, **beta (β) globulins**, and **gamma (γ) globulins**.

- 1 Like albumins, some alpha and beta globulins bind poorly water-soluble substances for transport in the plasma, but these globulins are highly specific as to which passenger they will bind and carry. Examples of substances carried by specific globulins include thyroid hormone (p. 248), cholesterol (p. 216), and iron (p. 685).
- 2 Many of the factors involved in the blood-clotting process are alpha or beta globulins.
- 3 Inactive, circulating proteins, which are activated as needed by specific regulatory inputs, belong to the

alpha globulin group (e.g., the alpha globulin *angiotensinogen* is activated to *angiotensin*, which plays an important role in regulating salt balance in the body; p. 576).

4 The gamma globulins are the *immunoglobulins* (antibodies), which are crucial to the body's defence mechanism (p. 475).

5 **Fibrinogen** is a key factor in blood clotting.

Plasma proteins are synthesized by the liver, with the exception of gamma globulins, which are produced by lymphocytes, one of the types of white blood cells.

FIGURE 10-1 Haematocrit and types of blood cells. The values given are for men. The average haematocrit for women is 42 percent, with plasma occupying 58 percent of the blood volume. Note the biconcave shape of the erythrocytes.

Check Your Understanding 10.1

1. Draw a centrifuged tube of whole blood, showing the packed cell volume and indicating the percentage occupied by plasma, by erythrocytes, and by the buffy coat in a normal man.
2. List the functions of plasma proteins.

10.3 Erythrocytes

Each millilitre of blood contains about 5 billion **erythrocytes** (**red blood cells or RBCs**) on average, which is commonly reported clinically in a **red blood cell count** as 5 million cells per cubic millimetre.

Structure and function

The shape and content of erythrocytes are ideally suited to carry out their primary function—namely, transporting oxygen and to a lesser extent carbon dioxide and hydrogen ion in the blood.

ERYTHROCYTE STRUCTURE

Erythrocytes are flat, disc-shaped cells indented in the middle on both sides, like a doughnut with a flattened centre instead of a hole (i.e., they are biconcave discs, 8 μm in diameter, 2 μm thick at the outer edges, and 1 μm thick in the centre) (see Figure 10-1). This unique shape contributes in two ways to the efficiency with which red blood cells perform their main function of oxygen transport in the blood: (1) the biconcave shape

provides a larger surface area for diffusion of oxygen across the membrane than would a spherical cell of the same volume; (2) the thinness of the cell enables oxygen to diffuse rapidly between the exterior and innermost regions of the cell.

Another structural feature that facilitates RBCs' transport function is the flexibility of their membrane. Red blood cells, whose diameter is normally 8 μm , can deform amazingly as they squeeze single file through capillaries as narrow as 3 μm in diameter. Because they are extremely pliant, RBCs can travel through the narrow, tortuous capillaries to deliver their oxygen cargo at the tissue level without rupturing in the process.

The most important anatomic feature that enables RBCs to transport oxygen is the haemoglobin they contain. Let's look at this unique molecule in more detail.

PRESENCE OF HAEMOGLOBIN

Haemoglobin is found only in red blood cells. A haemoglobin molecule has two parts: (1) the **globin** portion, a protein made up of four highly folded polypeptide chains; and (2) four iron-containing, non-protein groups known as **heme groups**, each of which is bound to one of the polypeptides (► Figure 10-2). Each of the four iron atoms can combine reversibly with one O_2 molecule; thus, each haemoglobin molecule can pick up four O_2 passengers in the lungs. Because oxygen is poorly soluble in the plasma, 98.5 percent of the oxygen carried in the blood is bound to haemoglobin (p. 532).

Haemoglobin is a pigment (i.e., it is naturally coloured). Because of its iron content, it appears reddish when combined with oxygen and bluish when deoxygenated. Fully oxygenated arterial blood is therefore red in colour, and venous blood, which has lost some of its O_2 load at the tissue level, appears much darker, but is still red.

► **FIGURE 10-2 Haemoglobin molecule.** A haemoglobin molecule consists of four highly folded polypeptide chains (the globin portion) and four iron-containing heme groups.

In addition to carrying oxygen, haemoglobin can combine with the following:

1. *Carbon dioxide*. Haemoglobin helps transport this gas from the tissue cells back to the lungs (p. 538).
2. *The acidic hydrogen ion (H^+)* portion of ionized carbonic acid, which is generated at the tissue level from carbon dioxide. Haemoglobin buffers this acid so that it minimally alters the pH of the blood (p. 625).
3. *Carbon monoxide (CO)*. This gas is not normally in the blood, but if inhaled, it preferentially occupies the O_2 -binding sites on haemoglobin, causing CO poisoning.
4. *Nitric oxide (NO)*. In the lungs, the vasodilator nitric oxide binds to haemoglobin. This NO is released at the tissues, where it relaxes and dilates the local arterioles (p. 399). This vasodilation helps ensure that the oxygen-rich blood can make its vital rounds and also helps stabilize blood pressure.

Therefore, haemoglobin plays the key role in O_2 transport and also contributes significantly to CO_2 transport and the pH-buffering capacity of blood. Furthermore, by toting along its own vasodilator, haemoglobin helps deliver the oxygen it is carrying. (Chapter 12 provides a detailed explanation of haemoglobin and its role in gas transport.)

Clinical Connections

Haemoglobin is the iron-containing molecule that transports oxygen

throughout the body. When someone has iron deficient anemia, there is a decrease in production of haemoglobin and, over time, this can lead to a decrease in the total amount of haemoglobin in the blood. This decreases the oxygen-carrying capacity of the blood. At rest, this may or may not be felt, but during exercise there is insufficient oxygen delivery to the working muscles, and you will fatigue faster than normal.

LACK OF NUCLEUS AND ORGANELLES

To maximize its haemoglobin content, a single erythrocyte is stuffed with more than 250 million haemoglobin molecules, excluding almost everything else. (That means each RBC can carry more than a billion O_2 molecules!) Red blood cells contain no nucleus, organelles, or ribosomes. During the cell's development, these structures are extruded to make room for more haemoglobin. Thus, a RBC is mainly a plasma membrane-enclosed sac full of haemoglobin.

KEY ERYTHROCYTE ENZYMES

Only a few crucial, non-renewable enzymes remain within a mature erythrocyte: glycolytic enzymes and carbonic anhydrase. The **glycolytic enzymes** are necessary for generating the energy needed to fuel the active-transport mechanisms involved in maintaining proper ionic concentrations within the cell. Paradoxically, even though erythrocytes are the vehicles for transporting oxygen to all other tissues of the body, for energy production they themselves cannot use the oxygen they are carrying. Lacking the mitochondria that house the enzymes for oxidative phosphorylation, erythrocytes must rely entirely on glycolysis for ATP formation.

The other important enzyme within RBCs, **carbonic anhydrase**, is critical in CO_2 transport. This enzyme catalyzes a key reaction that ultimately leads to the conversion of metabolically produced carbon dioxide into **bicarbonate ion (HCO_3^-)**, which is the primary form in which carbon dioxide is transported in the blood. Thus, erythrocytes contribute to CO_2 transport in two ways: by means of its carriage on haemoglobin and its carbonic anhydrase-induced conversion to bicarbonate.

Bone marrow

Each of us has a total of 25 trillion to 30 trillion RBCs streaming through our blood vessels at any given time (750 000 times more in number than the entire Canadian population)! Yet these vital gas-transport vehicles are short lived and must be replaced at the average rate of 2 million to 3 million cells per second (Appendix F lists normal reference values).

ERYTHROCYTES' SHORT LIFESPAN

The price erythrocytes pay for their generous content of haemoglobin, which requires the exclusion of the usual specialized intracellular machinery, is a short lifespan. Without DNA and RNA, red blood cells cannot synthesize proteins for cell repair, growth, and division or for renewing enzyme supplies. Equipped only with initial supplies synthesized before they extrude their nucleus, organelles, and ribosomes, RBCs survive an average of only 120 days, in contrast to nerve and muscle cells, which last a person's entire life. During its short lifespan of four months, each erythrocyte travels about 1125 km as it circulates through the vasculature.

As a red blood cell ages, its nonreparable plasma membrane becomes fragile and prone to rupture as the cell squeezes through tight spots in the vascular system. Most old RBCs meet their final demise in the **spleen**, because this organ's narrow, winding capillary network is a tight fit for these fragile cells. The spleen lies in the upper left part of the abdomen. In addition to removing most of the old erythrocytes from circulation, the spleen has a limited ability to store healthy erythrocytes in its pulpy interior, serves as a reservoir site for platelets, and contains an abundance of lymphocytes, a type of white blood cell.

ERYTHROPOIESIS

Erythrocytes cannot divide to replenish their own numbers, so the old ruptured cells must be replaced by the new cells produced in an erythrocyte factory—the **bone marrow**—which is the soft, highly cellular tissue that fills the internal cavities of bones. The bone marrow normally generates new red blood cells—by a process known as **erythropoiesis**—at a rate to keep pace with the demolition of old cells.

During intrauterine development, erythrocytes are produced first by the yolk sac and then by the developing liver and spleen, until the bone marrow is formed and takes over erythrocyte production exclusively. In children, most bones are filled with **red bone marrow**—capable of blood cell production. As a person matures fatty **yellow bone marrow**—incapable of erythropoiesis—gradually replaces red marrow, which remains only in a few isolated places, such as the sternum (breastbone), ribs, and upper ends of the long limb bones.

Red marrow not only produces RBCs but also is the ultimate source for leukocytes and platelets. Undifferentiated **pluripotent stem cells** reside in the red marrow, where they continuously divide and differentiate to give rise to each type of blood cells. These stem cells, the source of all blood cells, have now been isolated. The search was difficult, because stem cells are less than 0.1 percent of all cells in the bone marrow. Although a great deal of research remains to be done, this recent discovery may hold a key to a cure for a host of blood and immune disorders, as well as numerous other diseases.

The different types of immature blood cells, along with the stem cells, are intermingled in the red marrow at various stages of development. Once mature, the blood cells are released into the rich supply of capillaries that permeate the red marrow. Regulatory factors act on the *haemopoietic* (blood-producing) red marrow to govern the type and number of cells generated and discharged into the blood. Of the blood cells, the mechanism for regulating RBC production is the best understood. We consider this next.

Erythropoietin

O₂ transport in the blood is the erythrocytes' primary function. So you might logically suspect that the primary stimulus for increased erythrocyte production would be reduced O₂ delivery to the tissues. You would be correct; however, low O₂ levels do not stimulate erythropoiesis by acting directly on the red bone marrow. Instead, reduced O₂ delivery to the kidneys stimulates them to secrete the hormone **erythropoietin (EPO)** into the blood, and this hormone, in turn, stimulates erythropoiesis by the bone marrow (► Figure 10-3).

Erythropoietin acts on derivatives of undifferentiated stem cells that are already committed to becoming RBCs, stimulating their proliferation and maturation into mature erythrocytes. This increased erythropoietic activity elevates the number of circulating RBCs, thereby increasing O₂-carrying capacity of the blood and restoring O₂ delivery to the tissues to normal. Once normal O₂ delivery to the kidneys is achieved, erythropoietin secretion is reduced until needed again. In this way, erythrocyte production is normally balanced against the destruction or loss of these cells so that O₂-carrying capacity in the blood stays fairly constant. In severe loss of RBCs, as in haemorrhage or abnormal destruction of young circulating erythrocytes, the rate of erythropoiesis can be increased to more than six times the normal level.

The preparation of an erythrocyte for its departure from the marrow involves several steps, such as synthesis of haemoglobin and extrusion of the nucleus and organelles. Cells closest to maturity need a few days to reach maturity and be released into the blood in response to erythropoietin, and the less-developed and newly proliferated cells may take up to several weeks to reach maturity. Therefore, the time required for complete replacement of lost RBCs depends on how many are needed to return the number to normal. (When you donate blood, your circulating erythrocyte supply is replenished in less than a week.)

Blood types

There are a minimum of 30 relatively universal antigens (proteins) and many uncommon antigens associated with human blood cells. Many of these are unable to cause an antigen–antibody reaction. However, the most common and important blood typing is the A, B, and O antigen system (**ABO system**), which is associated with the antigens present on the surface of the red blood cell (erythrocytes). Scientist Karl Landsteiner is credited as having discovered the ABO blood typing

► FIGURE 10-3 Control of erythropoiesis

system in about 1900 and later was awarded the Nobel Prize in Physiology or Medicine for his work.

A second system of blood typing is the Rh (Rhesus) system. In this system, the transfusion reaction occurs at a slower rate. Antibodies associated with blood types are the classic example of “natural antibodies,” although natural immunity is actually a special case of active immunity. Let’s see how blood typing works.

ABO BLOOD TYPES

The surface membranes of human erythrocytes contain inherited antigens that vary depending on blood type; because these antigens are inherited, they can also be used to study parentage. Within the major blood group system, the ABO system, the erythrocytes of people with type A blood contain A antigens, those with type B blood contain B antigens, those with type AB blood have both A and B antigens, and those with type O blood do not have any A or B red blood cell surface antigens.

Antibodies against erythrocyte antigens not present on the body’s own erythrocytes begin to appear in human plasma after a baby is about six months of age. Accordingly, the plasma of type A blood contains anti-B antibodies, type B blood contains anti-A antibodies, no antibodies related to the ABO system are present in type AB blood, and both anti-A and anti-B antibodies are present in type O blood. These antigens and antibodies are able to cause a blood transfusion reaction, which typically occurs in the plasma of the blood. The antibodies bind with the erythrocytes’ antigens, causing agglutination of the red cells (see Transfusion Reaction). Because of this process, the antigens associated with the erythrocytes are called *agglutinogens*, and the antibodies are called *agglutinins*.

Typically, one would expect antibody production against A or B antigen to be induced only if blood containing the alien antigen were injected into the body. However, high levels of these antibodies are found in the plasma of people who have never been exposed to a different type of blood. Consequently, these were considered naturally occurring antibodies—that is, produced without any known exposure to the antigen.

Scientists now realize that people are unknowingly exposed at an early age to small amounts of A- and B-like antigens associated with common intestinal bacteria. The bacteria are believed to make their way into the body via ingested food from our daily diet. Antibodies produced against the foreign antigen will then react when the wrong blood type (and associated surface antigen) is transfused into the body. This is considered a secondary immune response by the adapted division of the immune system; the first response occurred during the initial exposure to the intestinal bacteria that generated the antibodies (producing the memory cells). Your own blood type and its surface antigens are not identified as foreign (i.e., the A antigen in a type A person) because of clonal deletion.

Therefore, the test to establish blood type begins with a blood sample being drawn from a vein and mixed with antibodies against types A and B blood, then the sample is checked to see whether or not the blood cells agglutinate. If agglutination takes place, it means the blood reacted with one of the antibodies. In the second step, known as back typing, the non-cell liquid part of your blood is mixed with blood that is known to be type A

and type B. These two steps can accurately determine your ABO blood type. Blood typing then proceeds to testing for Rh factor to tell whether or not you have an Rh antigen (to be discussed next) on the surface of your erythrocytes.

RH BLOOD TYPES

The Rh blood group system (an erythrocyte antigen first observed in Rhesus [Rh] monkeys) consists of about 50 defined blood-group antigens; the six primary antigen groups are D, C, E, d, c, and e. This classification system is termed the CDE system developed by Fisher and Race (Fisher–Race), and is the most commonly used nomenclature. A person with C antigen will not have c antigen, and the same pattern follows for the other antigens. The D antigen is frequently found in the population and is the most antigenic, and thus most important. The terms **Rh factor**—Rh positive (+) and Rh negative (–)—refer to the D antigen. The essence of the Fisher–Race system is that persons either have, or do not have, Rh factor on the surface of their erythrocytes. If they have the Rh⁺ factor, they are considered Rh⁺, and those without it are termed Rh[–].

In contrast to the ABO blood type, immunization against Rh can usually only occur through blood transfusion or placental exposure during pregnancy. This is because it requires an enormous exposure to the Rh factor to elicit a reaction. Anti-Rh antibodies are produced only by Rh[–] individuals, and if such people are exposed to foreign Rh antigens present in Rh⁺ blood, they become sensitized to the Rh⁺ antigen. A subsequent transfusion of Rh[–] blood could produce a transfusion reaction. Rh⁺ individuals, in contrast, never produce antibodies against the Rh[–] factor that they themselves possess. Therefore, Rh[–] people should be given only Rh[–] blood, whereas Rh⁺ people can safely receive either Rh[–] or Rh⁺ blood. The Rh factor is of particular medical importance when an Rh[–] mother develops antibodies against the erythrocytes of an Rh⁺ fetus she is carrying: a condition known as erythroblastosis fetalis, or haemolytic disease of the newborn. It was in 1939 that Drs. Levine and Stetson published the clinical consequences of nonrecognized Rh factor, resulting in a haemolytic transfusion reaction in a newborn.

Once a person’s blood is typed as A, B, O, or AB, each blood type is further characterized as Rh⁺ or Rh[–]. For example, if you have blood type B and are Rh⁺, you are said to be B-positive (B⁺). Generally, about 85 percent of all people are Rh⁺, and the remaining are said to be Rh[–].

TRANSFUSION REACTION

If a person is given blood of an incompatible type, two different antigen–antibody interactions take place. By far the more serious consequences arise from the effect of the antibodies in the recipient’s plasma on the incoming donor erythrocytes. The effect of the donor’s antibodies on the recipient’s erythrocyte-bound antigens is less important, unless a large amount of blood is transfused, because the donor’s antibodies are so diluted by the recipient’s plasma that little red blood cell damage takes place in the recipient.

Antibody interaction with erythrocyte-bound antigen may result in agglutination (clumping) or haemolysis (rupture) of the attacked red blood cells. Agglutination and haemolysis of

donor red blood cells by antibodies in the recipient's plasma can lead to a sometimes fatal **transfusion reaction** (▶ Figure 10-4). Agglutinated clumps of incoming donor cells can plug small blood vessels. In addition, one of the most lethal consequences of mismatched transfusions is acute kidney failure, caused by the release of large amounts of haemoglobin from damaged donor erythrocytes. If the free haemoglobin in the plasma rises above a critical level, it will precipitate in the kidneys and block the urine-forming structures, leading to acute kidney shutdown.

▶ **FIGURE 10-4 Transfusion reaction.** A transfusion reaction resulting from type B blood being transfused into a recipient with type A blood

UNIVERSAL BLOOD DONORS AND RECIPIENTS

Because type O individuals have no A or B antigens, their erythrocytes will not be attacked by either anti-A or anti-B antibodies, so they are considered **universal donors**. Their blood can be transfused into people of any blood type. However, type O individuals can receive only type O blood, because the anti-A and anti-B antibodies in their plasma will attack either A or B antigens in incoming blood. In contrast, type AB individuals are called **universal recipients**. Lacking both anti-A and anti-B antibodies, they can accept donor blood of any type, although they can donate blood only to other AB people. Because their erythrocytes have both A and B antigens, their cells would be attacked if transfused into individuals with antibodies against either of these antigens.

The terms *universal donor* and *universal recipient* are misleading, however. In addition to the ABO system, many other erythrocyte antigens and plasma antibodies can cause transfusion reactions, the most important of which is the Rh factor. Remember that those with Rh⁻ blood are *universal donors*, but those with Rh⁺ blood can only donate to other Rh⁺ persons.

RETICULOCYTES

When demands for RBC production are high (e.g., following haemorrhage), the bone marrow may release large numbers of immature erythrocytes, known as **reticulocytes**, into the blood to quickly meet the need. Reticulocytes develop and mature in the red bone marrow, following which the reticulocytes circulate for about 24 hours in the bloodstream before transforming into a mature RBC. These immature cells can be recognized by staining techniques that make visible the residual ribosomes and organelle remnants that have not yet been extruded. Automated laser-marking counters are used with a fluorescent dye to accurately count the reticulocytes. Their presence above the normal level of 0.5 to 1.5 percent of the total number of circulating erythrocytes indicates a high rate of erythropoietic activity. At very rapid rates, more than 30 percent of the circulating red cells may be at the immature reticulocyte stage.

SYNTHETIC ERYTHROPOIETIN

Researchers have identified the gene that directs erythropoietin synthesis, so this hormone can now be produced in a laboratory. Laboratory-produced erythropoietin has currently become biotechnology's single-biggest money-maker, with sales exceeding \$1 billion annually. This hormone is often used to boost RBC production in patients with suppressed erythropoietic activity, such as those with kidney failure or those undergoing chemotherapy for cancer. (Chemotherapy drugs interfere with the rapid cell division characteristic of both cancer cells and the developing RBCs.) Furthermore, the ready availability of this hormone has diminished the need for blood transfusions. For example, transfusion of a surgical patient's own previously collected blood, coupled with erythropoietin to stimulate further RBC production, has reduced the use of donor blood by as much as 50 percent in some hospitals. (See Concepts Challenges, and Controversies for an update on other alternatives to whole-blood transfusions under investigation.)

Anaemia

Despite control measures, oxygen-carrying capacity cannot always be maintained to meet tissue needs. The term **anaemia** refers to a below-normal O_2 -carrying capacity of the blood and is characterized by a low haematocrit (► Figure 10-5a and 10-5b). It can be brought about by a decreased rate of erythropoiesis, excessive losses of erythrocytes, or a deficiency in the haemoglobin content of erythrocytes. The various causes of anaemia can be grouped into six categories:

1. **Nutritional anaemia** is caused by a dietary deficiency of a factor needed for erythropoiesis. The production of RBCs depends on an adequate supply of essential raw ingredients, some of which are not synthesized in the body but must be provided by dietary intake. For example, *iron deficiency anaemia* (see Clinical Connection in Section 10.3) occurs when not enough iron is available for synthesizing haemoglobin.
2. **Pernicious anaemia** is caused by an inability to absorb enough ingested vitamin B_{12} from the digestive tract. Vitamin B_{12} is essential for normal RBC production and maturation. It is abundant in a variety of foods. The problem is a deficiency of *intrinsic factor*, a special substance secreted by the lining of the stomach (p. 664). Vitamin B_{12} can be absorbed from the intestinal tract only when this nutrient is bound to intrinsic factor. When intrinsic factor is deficient, not enough ingested vitamin B_{12} is absorbed. The resulting impairment of RBC production and maturation leads to anaemia.
3. **Aplastic anaemia** is caused by failure of the bone marrow to produce enough RBCs, even though all ingredients necessary for erythropoiesis are available. Reduced erythropoietic capability can be caused by destruction of red bone marrow by toxic chemicals (such as benzene), heavy exposure to radiation (e.g., fallout from a nuclear bomb explosion, or excessive exposure to X-rays), invasion of the marrow by cancer cells, or chemotherapy for cancer. The destructive process may selectively reduce the marrow's output of erythrocytes, or it may reduce the productive capability for leukocytes and platelets as well. The anaemia's severity depends on the extent to which erythropoietic tissue is destroyed; severe losses are fatal.
4. **Renal anaemia** may result from kidney disease. Because erythropoietin from the kidneys is the primary stimulus for promoting erythropoiesis, inadequate erythropoietin secretion by diseased kidneys leads to insufficient RBC production.
5. **Haemorrhagic anaemia** is caused by losing a lot of blood. The loss can be either acute, such as a bleeding wound, or chronic, such as excessive menstrual flow.
6. **Haemolytic anaemia** is caused by the rupture of too many circulating erythrocytes. **Haemolysis**, the rupture of RBCs, occurs either because otherwise normal cells are induced to rupture by external factors, as in the invasion of RBCs by *malaria* parasites, or because the cells are defective, as in sickle cell disease. **Sickle cell disease** is the best-known example among various hereditary abnormalities of erythrocytes that make these cells very fragile. It

affects about 1 in 650 persons of African descent. In this condition, a defective type of haemoglobin joins together to form rigid chains that make the RBC stiff and unnaturally shaped, like a crescent or sickle (► Figure 10-6). Unlike normal erythrocytes, these deformed RBCs tend to clump together. The resultant logjam blocks blood flow through small vessels, leading to pain and tissue damage at the affected site. Furthermore, the defective erythrocytes are fragile and prone to rupture, even as young cells, as they travel through the narrow splenic capillaries. Despite an accelerated rate of erythropoiesis triggered by the constant excessive loss of RBCs, production may not be able to keep pace with the rate of destruction, and anaemia may result.

10

► **FIGURE 10-5 Haematocrit under various circumstances** (a) Normal haematocrit. (b) The haematocrit is lower than normal in anaemia because of too few circulating erythrocytes; and (c) above normal in polycythaemia because of excess circulating erythrocytes. (d) The haematocrit can also be elevated during dehydration, when the normal number of circulating erythrocytes is concentrated in a reduced plasma volume.

Polycythaemia

Poiseuille's law states that the greater the viscosity of blood, the greater the reduction in flow within a vessel, if all other variables remain constant. We can use the

In Search of a Blood Substitute

ONE OF THE HOTTEST MEDICAL CONTESTS of the last two decades has been the race to develop a universal substitute for human blood that is safe, inexpensive, and disease free, and that has a long shelf life.

Need for a Blood Substitute

In Canada, over 2000 units of blood are required in hospitals every day. With only 3.5 percent of eligible Canadians actually donating blood, regional shortages of particular blood types occur. Such shortages are only expected to become more widespread as the number of blood donors continues to decline at the same time that the number of senior citizens, the group of people who most often need transfusions, continues to grow. The benefits for society of a safe blood substitute that could be administered without regard for the recipient's blood type are great, as will be the profits for the manufacturer of the first successful product. Experts estimate that the world market for a good blood substitute, more accurately called an *oxygen therapeutic*, may be as much as \$10 billion per year.

Researchers began working on blood substitutes in the 1960s, but the search for an alternative to whole-blood transfusions was given new impetus in the 1980s by the rising incidence of AIDS, the tainted blood scandal, and the concomitant concern over the safety of the nation's blood supply. Infectious diseases—such as AIDS, viral hepatitis, and West Nile virus—can be transmitted from infected blood donors to recipients of blood transfusions. Furthermore, restrictions have been placed on potential donors who lived or travelled in Europe during the time mad cow disease hit the beef industry. Although careful screening of our blood supply minimizes the possibility that infectious diseases will be transmitted through transfusion, the public remains wary and would welcome a safe substitute.

Eliminating the risk of disease transmission is only one advantage of finding an alternative to whole-blood transfusion. Whole blood must be kept refrigerated, and even then it has a shelf life of only 42 days. Also, transfusion of whole blood requires blood typing and cross-matching, which cannot be done at the scene of an accident or on a battlefield.

Major Approaches

The goal is not to find a replacement for whole blood but to duplicate its O_2 -carrying capacity. The biggest need for blood

transfusions is to replace acute blood loss in accident victims, surgical patients, and wounded soldiers. These individuals require short-term replenishment of blood's O_2 -carrying capacity until their own bodies synthesize replacement erythrocytes. The many other important elements in blood are not as immediately critical in sustaining life as is the haemoglobin within the RBCs. Problematically, red blood cells are the whole-blood component that requires refrigeration, has a short shelf life, and bears the markers for the various blood types.

Therefore, the search for a blood substitute has focused on two major possibilities: (1) haemoglobin products that exist outside a RBC and can be stored at room temperature for up to six months to a year, and (2) chemically synthesized products that serve as artificial haemoglobin by dissolving large amounts of oxygen when O_2 levels are high (as in the lungs) and releasing it when O_2 levels are low (as in the tissues). A variety of potential blood substitutes are in various stages of development. Some have reached the stage of clinical trials, but no products have yet reached the market, although they are getting close. Let's examine each of these major approaches.

Haemoglobin Products

By far the greatest number of research efforts has focused on manipulating the structure of haemoglobin so that it can be effectively and safely administered as a substitute for whole-blood transfusions. If appropriately stabilized and suspended in saline solution, haemoglobin could be injected to bolster the O_2 -carrying capacity of the recipients' blood no matter what their blood type. The following strategies are among those being pursued to develop a haemoglobin product:

- One problem is that haemoglobin behaves differently when it is outside RBCs. "Naked" haemoglobin splits into halves that do not release oxygen for tissue use as readily as normal haemoglobin does. As well, these haemoglobin fragments can cause kidney damage. A cross-binding reagent has been developed that keeps haemoglobin molecules intact when they are outside the confines of red blood cells, thereby surmounting one major obstacle to administering free haemoglobin.

viscosity of water as a touchstone for that of blood, as blood is approximately three times as viscous as water. The viscosity of blood is largely dependent on the number of suspended RBCs in the blood. Consequently, if the number of RBCs increases, the frictional drag between the RBCs and the vessel's wall increases. It is this frictional drag that determines viscosity;

the greater the blood's viscosity, the larger the reduction in the blood flow.

A common method used to measure the number of RBCs in blood is haematocrit. If a healthy person has a haematocrit of 42 percent, then 42 percent of the person's blood volume consists of cells (primarily RBCs), and the remaining portion

- Some products under investigation are derived from outdated, donated human blood. Instead of the blood being discarded, its haemoglobin is extracted, purified, sterilized, and chemically stabilized. However, this strategy relies on the continued practice of collecting human blood donations.
- Several products use cows' blood as a starting point. Bovine haemoglobin is readily available from slaughterhouses, is cheap, and can be treated for administration to humans. A big concern with these products is the potential of introducing into humans unknown disease-causing microbes that might be lurking in the bovine products.
- A potential candidate as a blood substitute is genetically engineered haemoglobin that bypasses the ongoing need for human donors or the risk of spreading disease from cows to humans. Genetic engineers can insert the gene for human haemoglobin into bacteria, which act as a factory to produce the desired haemoglobin product. A drawback for genetically engineered haemoglobin is the high cost involved in operating the facilities.
- One promising strategy encapsulates haemoglobin within liposomes—membrane-wrapped containers—similar to real haemoglobin-stuffed, plasma membrane-enclosed RBCs. These so-called *neo red cells* await further investigation.
- By changing surgical practices, the medical community has reduced the need for transfusions. These blood-saving methods include recycling a patient's own blood during surgery (collecting lost blood, then reinfusing it); using less invasive and therefore less bloody surgical techniques; and treating the patient with blood-enhancing erythropoietin prior to surgery.
- The necessity of matching blood types for transfusions is a major reason for waste at blood banks. Transfusion of mismatched blood causes a serious, even fatal reaction (p. 439). Therefore, a blood bank may be discarding stocks of one blood type that has gone unused while facing a serious shortage of another type. The various blood types are distinguished by differences in the short sugar-chain markers that project from the red cell's plasma membrane (p. 439). Mismatched identity markers are the target for attack in a transfusion reaction. Researchers are making considerable progress in their search for enzymes that can cleave the identity markers away from RBCs, thereby converting them all into a type that could be safely transfused into anyone. Such a product would reduce the current wastage.
- Other investigators are seeking ways to prolong the life of RBCs, either in a blood bank or in patients, thus reducing the need for fresh, transfusable blood.

As this list of strategies attests, considerable progress has been made toward developing a safe, effective alternative to whole-blood transfusions. Yet after more than three decades of intense effort, considerable challenges remain, and no ideal solution has been found.

Synthetic Oxygen Carriers

Other researchers are pursuing the development of chemical-based strategies that rely on *perfluorocarbons (PFCs)*, which are synthetic O_2 -carrying compounds. PFCs are completely inert, chemically synthesized molecules that can dissolve large quantities of oxygen in direct proportion to the amount of oxygen breathed in. Because they are derived from a nonbiological source, PFCs cannot transmit disease. This, coupled with their low cost, makes them attractive as a blood substitute. Yet use of PFCs is not without risk. Their administration can cause flu-like symptoms, and because of poor excretion, they may be retained and accumulate in the body. Ironically, PFC administration poses the danger of causing O_2 toxicity by delivering too much oxygen to the tissues in uncontrolled fashion (p. 541).

Tactics to Reduce Need for Donated Blood

Other tactics besides blood substitutes aimed toward reducing the need for donated blood include the following:

is plasma. Normal haematocrit values for males and females are 42 percent and 38 percent, respectively. Haematocrit values may change under certain circumstances, such as disease or injection of recombinant EPO, as seen in some cases of blood doping. There is a benefit to increasing haematocrit in the form of increased haemoglobin and O_2 -carrying capacity, but

as haematocrit increases so does blood viscosity (Figure 10-7). One negative aspect of increased haematocrit is a reduced ability of the heart to circulate the blood (because of increased friction), thereby decreasing the timely delivery of oxygen to the tissues. Thus, there is a fine balance between the benefit of increased O_2 -carrying capacity and the reduced ability to circulate the

Sickle-shaped red blood cell

Normal-shaped red blood cell

► **FIGURE 10-6** Sickle-shaped red blood cell

oxygen. The condition of polycythaemia is associated with an increased haematocrit.

Polycythaemia, in contrast to anaemia, is characterized by too many circulating RBCs and an elevated haematocrit (see ► Figure 10-5c). There are two general types of polycythaemia, depending on the circumstances triggering the excess RBC production: primary polycythaemia and secondary polycythaemia.

Primary polycythaemia is caused by a tumour-like condition of the bone marrow in which erythropoiesis proceeds at an excessive, uncontrolled rate instead of being subject to the normal erythropoietin regulatory mechanism. The RBC count may reach 11 million cells/mm³ (normal is 5 million cells/mm³), and the haematocrit may be as high as 70 to 80 percent (normal is 42 to 45 percent). Inappropriate polycythaemia has harmful effects, however. The excessive number of red cells increases blood's viscosity up to five to seven times normal, causing the blood to flow very sluggishly, which may actually reduce O₂

delivery to the tissues (p. 387). The increased viscosity also increases the total peripheral resistance, which may elevate the blood pressure, thus increasing the workload of the heart, unless blood pressure control mechanisms can compensate (see ► Figure 9-14).

Secondary polycythaemia, in contrast, is an appropriate erythropoietin-induced adaptive mechanism to improve the blood's O₂-carrying capacity in response to a prolonged reduction in O₂ delivery to the tissues. It occurs normally in people living at high altitudes, where less oxygen is available in the atmospheric air, or people in whom O₂ delivery to the tissues is impaired by chronic lung disease or cardiac failure. The red cell count in secondary polycythaemia is usually lower than that in primary polycythaemia, typically averaging 6–8 million cells/mm³. The price paid for improved O₂ delivery is an increased viscosity of the blood.

An elevated haematocrit can occur when the body loses fluid but not erythrocytes, as in dehydration that accompanies heavy sweating or profuse diarrhoea (see ► Figure 10-5d). This is not a true polycythaemia, however, because the number of circulating RBCs is not increased. A normal number of erythrocytes is simply concentrated in a smaller plasma volume. This condition is sometimes termed **relative polycythaemia**.

Relative polycythaemia frequently occurs in weight-class sports, such as boxing, wrestling, judo, and rowing. In high school or university wrestling, average weekly body weight fluctuations commonly exceed 2.5 kg, 15 times a season over a 24-to-48-hour period, mostly because of dehydration. There have been reports of athletes decreasing body weight by 5 kg in less than five hours, all via dehydration. Typically, dehydration methods include diuretics, saunas, rubber suits, and running. The physiological effects of dehydration include reductions in plasma volume, cardiac output, peripheral blood flow (muscle and skin), sweating, thermoregulatory ability, and rate of stomach emptying. Physical performance also suffers. However, once rehydration takes place via the consumption of fluids, primarily water, these negative physiological changes are reversed as the body moves toward homeostasis (e.g., normal haematocrit and plasma volume).

10.4 Leukocytes

Leukocytes (white blood cells or WBCs) are the mobile units of the body's immune defence system (Appendix G lists normal reference values). **Immunity** is the body's ability to resist or eliminate potentially harmful foreign materials or abnormal cells. Leukocytes and their derivatives, along with a variety

of plasma proteins, make up the **immune system**, an internal defence system that recognizes and either destroys or neutralizes materials within the body that are foreign to the “normal self.” Specifically, the immune system (1) defends against invading **pathogens** (disease-producing microorganisms, such as bacteria and viruses); (2) identifies and destroys cancer cells that arise in the body; and (3) removes worn-out cells (such as aged red blood cells) and tissue debris (e.g., tissue damaged by trauma or disease). The latter is essential for wound healing and tissue repair.

Defence agents

To carry out their functions, leukocytes largely use a “seek out and attack” strategy; that is, they go to sites of invasion or tissue damage. The main reason WBCs are in the blood is to be rapidly transported from their site of production or storage to wherever they are needed.

Five types

Leukocytes lack haemoglobin, so they are colourless (i.e., white) unless specifically stained for microscopic visibility. Unlike erythrocytes, which are of uniform structure, identical function, and constant number, leukocytes vary in structure, function, and number. There are five different types of circulating leukocytes—neutrophils, eosinophils, basophils, monocytes, and lymphocytes—each with a characteristic structure and function. They are all somewhat larger than erythrocytes.

The five types of leukocytes fall into two main categories, depending on the appearance of their nuclei and the presence or absence of granules in their cytoplasm when viewed microscopically (► Figure 10-8). Neutrophils, eosinophils, and basophils are categorized as **polymorphonuclear granulocytes** (*polymorphonuclear* means “many-shaped nucleus”; *granulocyte* means “granule-containing cell”). Their nuclei are segmented into several lobes of varying shapes, and their cytoplasm contains an abundance of membrane-enclosed granules. The three types of granulocytes are distinguished on the basis of the varying affinity of their granules for dyes: *eosinophils* have an affinity for the red dye eosin; *basophils* preferentially take up a basic blue dye; and *neutrophils* are neutral, showing no dye preference. Monocytes and lymphocytes are known as **mononuclear agranulocytes** (*mononuclear* means “single nucleus”; *agranulocyte* means “cell lacking granules”). Both have a single, large, non-segmented nucleus and few granules. Monocytes are the larger of the two and have an oval or a kidney-shaped nucleus. *Lymphocytes*, the smallest of the leukocytes, characteristically have a large, spherical nucleus that occupies most of the cell.

Production

All leukocytes ultimately originate from the same undifferentiated multipotent (having many potentials) stem cells in the red bone marrow that also give rise to erythrocytes and platelets (► Figure 10-9). The cells destined to become leukocytes eventually differentiate into various committed cell lines and proliferate under the influence of appropriate stimulating factors. Granulocytes and monocytes are produced only in the bone marrow, which releases these mature leukocytes into the blood. Lymphocytes are originally derived from precursor cells in the bone marrow, but most new lymphocytes are actually produced by lymphocytes already in the **lymphoid tissues** (lymphocyte-containing), such as the lymph nodes and tonsils.

The total number of leukocytes normally ranges from 5 million to 10 million cells per millilitre of blood, with an average of 7 million cells/mL—expressed as an average **white blood cell count** of 7000/mm³ (■ Table 10-2). Leukocytes are the least numerous of the blood cells (about 1 white blood cell for every 700 red blood cells), not because fewer are produced but because they are merely in transit while in the blood. Normally, about two-thirds of the circulating leukocytes are granulocytes,

► **FIGURE 10-8 Peripheral blood smear.** The relative abundance of erythrocytes (red blood cells or RBCs) and leukocytes (white blood cells or WBCs) can be visualized in this blood smear. Background view is a blood smear under low magnification showing a singular leukocyte in the centre. (a) A clump of platelets (thrombocytes); (b) a neutrophil with lobulated nucleus (bottom) and a lymphocyte; (c) a lymphocyte with condensed chromatin and very little cytoplasm; (d) a monocyte with horseshoe-shaped nucleus; (e) an eosinophil with lobulated nucleus and pink granules in the cytoplasm; and (f) a basophil with lobulated nucleus and densely stained granules. Scale bar = 7 μm .

► **FIGURE 10-9** Blood cell production (haemopoiesis). All the blood cell types ultimately originate from the same undifferentiated pluripotent stem cells in the red bone marrow.

mostly neutrophils, whereas one-third is agranulocytes, predominantly lymphocytes (► Figure 10-8). However, the total number of white cells and the percentage of each type may vary considerably to meet changing defence needs. Depending on the type and extent of assault the body is combating, different types of leukocytes are selectively produced at varying rates. Chemical messengers arising from invaded or damaged tissues or from activated leukocytes themselves govern the rates of production of the various leukocytes. Specific hormones analogous to erythropoietin direct the differentiation and proliferation of each cell type. Some of these hormones have been identified and can be produced in the laboratory; an example is **granulocyte colony-stimulating factor**, which stimulates increased replication and

release of granulocytes, especially neutrophils, from the bone marrow. This achievement has opened up the ability to administer these hormones as a powerful new therapeutic tool to bolster a person's normal defence against infection or cancer.

FUNCTIONS AND LIFESPANS OF LEUKOCYTES

The following are the functions and lifespans of the **granulocytes**:

- **Neutrophils**—major function: phagocytosis. Furthermore, scientists recently discovered that neutrophils release a web of extracellular fibres, dubbed *neutrophil extracellular traps (NETs)*. These fibres contain bacteria-killing chemicals, enabling NETs to trap and then destroy bacteria extracellularly. As a result, neutrophils can destroy bacteria both intracellularly by phagocytosis and extracellularly via the NETs they release. Neutrophils are the first defenders against bacterial invasion, are very important in inflammatory responses, and act as scavengers to clean up debris.
-  **Clinical Note** As might be expected in view of these functions, an increase in circulating neutrophils (**neutrophilia**) typically accompanies acute bacterial infections. In fact, a differential WBC count (a determination of the proportion of each type of leukocyte present) can be useful in making an immediate, reasonably accurate prediction of whether an infection, such as pneumonia or meningitis, is of bacterial or viral origin. Obtaining a definitive answer as to the causative agent by culturing a sample of the infected tissue's fluid takes several days. Because an elevated neutrophil count is highly indicative of bacterial infection, it is appropriate to initiate antibiotic therapy long before the true causative agent is actually known. (Bacteria generally succumb to antibiotics, whereas viruses do not.)
- **Eosinophils**—major function: phagocytosis of parasites. An increase in circulating eosinophils (**eosinophilia**) is

■ **TABLE 10-2** Typical Human Blood Cell Counts

Cell Type	Concentration (per mL blood)	Count (per mm ³)
Erythrocytes	5 billion	5 million
Platelets	250 million	250 000
Leukocytes (WBC)	7 million	7000
<i>Neutrophils (60–70%)</i>		
<i>Lymphocytes (25–33%)</i>		
<i>Monocytes (2–6%)</i>		
<i>Eosinophils (1–4%)</i>		
<i>Basophils (0.25–0.5%)</i>		

associated with allergic conditions (such as asthma) and with internal parasite infestations (e.g., worms). Eosinophils attach to the worm and secrete substances that kill it.

- **Basophils**—major function: chemotactic factor production. They are quite similar structurally and functionally to **mast cells**, which never circulate in the blood, but instead are dispersed in connective tissue throughout the body. Researchers have shown that basophils arise from the bone marrow, whereas mast cells are derived from precursor cells in connective tissue. Both basophils and mast cells synthesize and store *histamine* and *heparin*: powerful chemical substances that can be released on appropriate stimulation. Histamine release is important in allergic reactions, whereas heparin speeds up removal of fat particles from the blood after a fatty meal. Heparin can also prevent clotting (coagulation) of blood samples drawn for clinical analysis and is used extensively as an anticoagulant drug, but whether it plays a physiological role in clot prevention is still debated.

Once released into the blood from the bone marrow, a granulocyte usually stays in transit in the blood for less than a day before leaving the blood vessels to enter the tissues, where it survives another three to four days unless it dies sooner in the line of duty.

By comparison, the functions and lifespans of the agranulocytes are as follows:

- **Monocytes**—major function: phagocytosis, antigen presentation, cytokine production, and cytotoxicity. They emerge from the bone marrow while still immature, and circulate for only a day or two before settling down in various tissues throughout the body. At their new residences, monocytes mature and greatly enlarge, becoming the large tissue phagocytes known as **macrophages** (*macro* means “large”; *phage* means “eater”). A macrophage’s lifespan may range from months to years, unless it is destroyed sooner while performing its phagocytic activity. A phagocytic cell can ingest only a limited amount of foreign material before it succumbs.
- **Lymphocytes**—major function: lymphocyte activation, cytokine production, antigen recognition, antibody production, memory, and cytotoxicity. There are two types of lymphocytes: B lymphocytes and T lymphocytes. **B lymphocytes (B cells)** produce *antibodies*, which circulate in the blood and are responsible for *antibody-mediated*, or *humoural*, *immunity*. An antibody binds with and marks for destruction (by phagocytosis or other means) the specific kinds of foreign matter, such as bacteria, that induced production of the antibody. **T lymphocytes (T cells)** do not produce antibodies; instead, they directly destroy their specific target cells by releasing chemicals that punch holes in the victim cells, a process called *cell-mediated immunity*. The target cells of T cells include body cells invaded by viruses and cancer cells. Lymphocytes live for about 100 to 300 days. During this period, most of them continually recycle among the lymphoid tissues, lymph, and blood, spending only a few hours at a time in the blood. Therefore, only a small part of the total lymphocytes are in transit in the blood at any given moment.

ABNORMALITIES IN LEUKOCYTE PRODUCTION

Even though levels of circulating leukocytes may vary, changes in these levels are normally controlled and adjusted according to the body’s needs. However, abnormalities in leukocyte production can occur that are not subject to control; that is, either too few or too many WBCs can be produced. The bone marrow can greatly slow down or even stop production of white blood cells when it is exposed to certain toxic chemical agents (such as benzene and anti-cancer drugs) or to excessive radiation. The most serious consequence is the reduction in professional phagocytes (neutrophils and macrophages), which greatly reduces the body’s defence capabilities against invading microorganisms. The only defence still available when the bone marrow fails is the immune capabilities of the lymphocytes produced by the lymphoid organs.

In **infectious mononucleosis**, not only does the number of lymphocytes (but not other leukocytes) in the blood increase, but also many of the lymphocytes are atypical in structure. This condition, which is caused by the *Epstein-Barr virus*, is characterized by pronounced fatigue, a mild sore throat, and low-grade fever. Full recovery usually requires a month or more.

Surprisingly, one of the major consequences of **leukaemia**, a cancerous condition that involves uncontrolled proliferation of WBCs, is inadequate defence capabilities against foreign invasion. In leukaemia, the WBC count may reach as high as 500 000/mm³, compared with the normal 7000/mm³, but because most of these cells are abnormal or immature, they cannot perform their normal defence functions. Another devastating consequence of leukaemia is displacement of the other blood cell lines in the bone marrow. This results in anaemia due to a reduction in erythropoiesis and in internal bleeding caused by a deficit of platelets. Platelets play a critical role in preventing bleeding from the myriad tiny breaks that normally occur in small blood vessel walls. Consequently, overwhelming infections and haemorrhage are the most common causes of death in leukemic patients. In the next section we examine the role of platelets in detail to show how they normally minimize the threat of haemorrhage.

2. State the function of each type of leukocyte.

10.5 | Platelets and Haemostasis

In addition to erythrocytes and leukocytes, **platelets (thrombocytes)** are a third type of cellular element in blood. An average of 250 million platelets are normally present in each millilitre of blood (range of 150 000 to 350 000 / m³).

Platelets

Platelets are not whole cells; instead, they are small cell fragments (about 2–4 μm in diameter) shed from the outer edges of extraordinarily large (up to 60 μm in diameter) bone marrow-bound cells known as **megakaryocytes** (► Figure 10-10; also see Figure 10-9). A single megakaryocyte typically produces about 1000 platelets. Megakaryocytes are derived from the same undifferentiated stem cells that give rise to the erythrocytic and leukocytic cell lines. Platelets are essentially detached vesicles containing pieces of megakaryocyte cytoplasm wrapped in plasma membrane.

Platelets remain functional for an average of 10 days, at which time they are removed from circulation by the tissue macrophages, especially those in the spleen and liver, and are replaced by newly released platelets from the bone marrow. The hormone **thrombopoietin**, produced by the liver, increases the number of megakaryocytes in the bone marrow and stimulates each megakaryocyte to produce more platelets. The factors that control thrombopoietin secretion and regulate the platelet level are currently under investigation.

Platelets do not leave the blood as WBCs do, but at any given time about one-third of them are in storage in blood-filled spaces in the spleen. These stored platelets can be released from the spleen into the circulating blood as needed (e.g., during haemorrhage) by sympathetically induced splenic contraction.

Because platelets are cell fragments, they lack nuclei. However, they have organelles and cytosolic enzyme systems that generate energy and synthesize secretory products, which they store in numerous granules dispersed throughout the cytosol. Furthermore, platelets contain high concentrations of actin and myosin, which enable them to contract. Their secretory and contractile abilities are important in haemostasis, the topic we now examine.

Haemostasis

Haemostasis is the arrest of bleeding from a broken blood vessel—that is, the stopping of haemorrhage (*haemo* means “blood”; *stasis* means “standing”). (Be sure not to confuse this with the term *homeostasis*.) For bleeding to take place from a vessel, there must be a break in the vessel wall and the pressure inside the vessel must be greater than the pressure outside it to force blood out through the defect.

The small capillaries, arterioles, and venules are often ruptured by minor traumas of everyday life; such traumas are the most common source of bleeding, although we often are not even aware that any damage has taken place. The body’s inherent haemostatic mechanisms normally are adequate to seal defects and stop blood loss through these small microcirculatory vessels.

 The much rarer occurrence of bleeding from medium- or large-size vessels usually cannot be stopped by the body’s haemostatic mechanisms alone. Bleeding from a severed artery is more profuse and therefore more dangerous than venous bleeding, because the outward driving pressure is greater in the arteries (i.e., arterial blood pressure is much higher than venous pressure). First-aid measures for a severed artery include applying to the wound external pressure that is greater than the arterial blood pressure to temporarily halt the bleeding until the torn vessel can be surgically closed. Haemorrhage from a traumatized vein can often be stopped simply by elevating the bleeding body part to reduce gravity’s effects on pressure in the vein (p. 416). If the accompanying drop in venous pressure is not enough to stop the bleeding, mild external compression is usually adequate.

Haemostasis involves three major steps: (1) *vascular spasm*, (2) *formation of a platelet plug*, and (3) *blood coagulation (clotting)*. Platelets play a pivotal role in haemostasis. They obviously play a major part in forming a platelet plug, but they also contribute significantly to the other two steps.

Vascular spasm

A cut or torn blood vessel immediately constricts. The underlying mechanism is unclear but is thought to be an intrinsic response triggered by a paracrine released locally from the inner lining (endothelium) of the injured vessel. This constriction, or **vascular spasm**, slows blood flow through the defect and thus minimizes blood loss. Also, as the opposing endothelial surfaces of the vessel are pressed together by this initial vascular spasm, they become sticky and adhere to each other, further sealing off the damaged vessel. These physical measures alone cannot completely prevent further blood loss, but they minimize blood flow through the break in the vessel until the other haemostatic measures can actually plug up the hole.

Platelet aggregation

Platelets normally do not stick to the smooth endothelial surface of blood vessels, but when this lining is disrupted because of vessel injury, platelets become activated by the exposed *collagen*, which is a fibrous protein in the underlying connective tissue.

- 1 Platelets adhere to and are activated by exposed collagen at the site of vessel injury.
- 2 Activated platelets release ADP and thromboxane A_2 .
- 3 These chemical messengers work together to activate other platelets passing by.
- 4 Newly activated platelets aggregate onto growing platelet plug and release even more platelet-attracting chemicals.
- 5 Normal (uninjured) endothelium releases prostacyclin and nitric oxide, which inhibit platelet aggregation, so platelet plug is confined to site of injury.

FIGURE 10-11 Formation of a platelet plug. Platelets aggregate at a vessel defect through a positive-feedback mechanism involving the release of adenosine diphosphate (ADP) and thromboxane A_2 from platelets, which stick to exposed collagen at the site of the injury. Platelets are prevented from aggregating at the adjacent normal vessel lining by the release of prostacyclin and nitric oxide from the undamaged endothelial cells.

When activated, platelets quickly adhere to the collagen and form a haemostatic **platelet plug** at the site of the defect. Once platelets start aggregating, they release several important chemicals from their storage granules. Among these chemicals is *adenosine diphosphate (ADP)*, which causes the surface of nearby circulating platelets to become sticky so that they adhere to the first layer of aggregated platelets. These newly aggregated platelets release more ADP, which causes more platelets to pile on, and so on. In this way, a plug of platelets rapidly builds up at the defect site in a positive-feedback fashion (► Figure 10-11). Activation of platelets by ADP also stimulates platelets to release another prothrombotic factor, *thromboxane A_2* . This released thromboxane A_2 enhances the positive-feedback pathway by further enhancing platelet recruitment and ADP release, as well as by directly stimulating platelet aggregation.

Given the self-perpetuating nature of platelet aggregation, why doesn't the platelet plug continue to develop and expand over the surface of the adjacent normal vessel lining? A key reason is that ADP and other chemicals released by the activated platelets stimulate the release of *prostacyclin* and *nitric oxide* from the adjacent normal endothelium. Both these chemicals profoundly inhibit platelet aggregation. Thus, the platelet plug is limited to the defect and does not spread to the nearby undamaged vascular tissue (► Figure 10-11).

The aggregated platelet plug not only physically seals the break in the vessel but also performs three other important roles. (1) The actin-myosin complexes within the aggregated platelets contract to compact and strengthen what was originally a fairly loose plug. (2) The chemicals released from the platelet plug include several powerful vasoconstrictors (serotonin, epinephrine, and thromboxane A_2), which induce profound constriction of the affected vessel to reinforce the initial vascular spasm. (3) The platelet plug releases other chemicals that enhance blood coagulation, the next step of haemostasis. Although the platelet-plugging mechanism alone is often enough to seal the myriad minute tears in capillaries and other small vessels that occur many times daily, larger holes in vessels require the formation of a blood clot to completely stop the bleeding.

Clot formation

Blood coagulation, or **clotting**, is the transformation of blood from a liquid into a solid gel. Formation of a clot on top of the platelet plug strengthens and supports the plug, reinforcing the seal over a break in a vessel. Furthermore, as blood in the vicinity of the vessel defect solidifies, it can no longer flow. Clotting is the body's most powerful haemostatic mechanism. It is required to stop bleeding from all but the most minute defects.

► **FIGURE 10-12** Erythrocytes trapped in the fibrin meshwork of a clot

CLOT FORMATION

The ultimate step in clot formation is the conversion of fibrinogen—a large, soluble plasma protein produced by the liver and normally always present in the plasma—into **fibrin**, an insoluble, threadlike molecule. This conversion into fibrin is catalyzed by the enzyme **thrombin** at the site of the injury. Fibrin molecules adhere to the damaged vessel surface, forming a loose, netlike meshwork that traps blood cells, including aggregating platelets. The resulting mass, or **clot**, typically appears red because of the abundance of trapped RBCs, but the foundation of the clot is formed of fibrin derived from the plasma (► Figure 10-12). Except for platelets, which play an important role in ultimately bringing about the conversion of fibrinogen to fibrin, clotting can take place in the absence of all other blood cells.

The original fibrin web is rather weak, because the fibrin strands are only loosely interlaced. However, chemical linkages rapidly form between adjacent strands to strengthen and stabilize the clot meshwork. This cross-linkage process is catalyzed by a clotting factor known as **factor XIII (fibrin-stabilizing factor)**, which normally is present in the plasma in an inactive form.

ROLES OF THROMBIN

Thrombin, in addition to (1) converting fibrinogen into fibrin, also (2) activates factor XIII to stabilize the resultant fibrin mesh, (3) acts in a positive-feedback fashion to facilitate its own formation, and (4) enhances platelet aggregation, which in turn is essential to the clotting process (► Figure 10-13).

Thrombin converts the ever-present fibrinogen molecules in the plasma into a blood-staunching clot, so it must normally be absent from the plasma, except in the vicinity of vessel damage. Otherwise, blood would always be coagulated—a situation incompatible with life. How can thrombin normally be absent from the plasma, yet be readily available to trigger fibrin formation when a vessel is injured? The solution lies in thrombin's existence in the plasma in the form of an inactive precursor called **prothrombin**. What converts prothrombin into thrombin when blood clotting is desirable? This conversion involves the clotting cascade.

THE CLOTTING CASCADE

Yet another activated plasma clotting factor, **factor X**, converts prothrombin to thrombin; factor X itself is normally present in the blood in an inactive form and must be converted into its active form by still another activated factor, and so on. Altogether, 12 plasma clotting factors participate in essential steps that lead to the final conversion of fibrinogen into a stabilized fibrin mesh (► Figure 10-14). These factors are designated by Roman numerals in the order they were discovered, not in the order they participate in the clotting process. Most of these clotting factors are plasma

1 Thrombin, a component of the clotting cascade, plays multiple roles in haemostasis:

- 1a** It stimulates conversion of fibrinogen to fibrin.
- 1b** It activates the factor that stabilizes the fibrin meshwork of the clot.
- 1c** It enhances activation of more prothrombin into thrombin through positive feedback.
- 1d** It enhances platelet aggregation.

2 Through positive feedback, aggregated platelets secrete PF3, which stimulates the clotting cascade that results in thrombin activation.

► **FIGURE 10-13** Roles of thrombin in haemostasis

proteins synthesized by the liver. One consequence of liver disease is that clotting time is prolonged due to a reduced production of clotting factors. Normally, they are always present in the plasma in an inactive form, such as fibrinogen and prothrombin. In contrast to fibrinogen, which is converted into insoluble fibrin strands, prothrombin and the other precursors act as proteolytic (protein-splitting) enzymes when converted to their active form. These enzymes activate other specific factors in the clotting sequence. Once the first factor in the sequence is activated, it activates the next factor, and so on, in a series of sequential reactions known as the **clotting cascade**; this continues until thrombin catalyzes the final conversion of fibrinogen into fibrin. Several of these

steps require the presence of plasma calcium and *platelet factor 3 (PF3)*, a phospholipid secreted by the aggregated platelet plug. Thus, platelets also contribute to clot formation.

INTRINSIC AND EXTRINSIC PATHWAYS

The clotting cascade may be triggered by the *intrinsic pathway* or the *extrinsic pathway*:

- The **intrinsic pathway** precipitates clotting within damaged vessels as well as clotting of blood samples in test tubes. All elements necessary to bring about clotting by means of the intrinsic pathway are present in the blood. This pathway, which involves seven separate steps (shown in blue in Figure 10-14), is set off when **factor XII (Hageman factor)**

FIGURE 10-14 Clot pathways. The intrinsic clotting pathway (in blue) is initiated when factor XII (Hageman factor) is activated by contact with exposed collagen at a damaged vessel surface or by contact with a foreign surface. This pathway brings about clotting within damaged vessels and clotting of blood samples in test tubes. The shorter extrinsic clotting pathway (in grey) is initiated when factor X, a factor activated halfway through the intrinsic pathway, is activated by tissue thromboplastin released from damaged tissue. The extrinsic pathway causes clotting of blood that escapes from blood vessels into the surrounding tissue during injury. The steps in the two pathways are identical from factor X on (in blue-grey).

is activated by coming into contact with either exposed collagen in an injured vessel or a foreign surface, such as a glass test tube. Remember that exposed collagen also initiates platelet aggregation. In this way, the formation of a platelet plug and the chain reaction leading to clot formation are simultaneously set in motion when a vessel is damaged. Furthermore, these complementary haemostatic mechanisms reinforce each other. The aggregated platelets secrete PF3, which is essential for the clotting cascade that, in turn, enhances further platelet aggregation (► Figure 10-15; also see Figure 10-13).

- The **extrinsic pathway** takes a shortcut and requires only four steps (shown in grey in Figure 10-14). This pathway, which requires contact with tissue factors external to the blood, initiates clotting of blood that has escaped into the tissues. When a tissue is traumatized, it releases a protein complex known as **tissue thromboplastin**. Tissue thromboplastin directly activates factor X, thereby bypassing all preceding steps of the intrinsic pathway. From this point on, the two pathways are identical.

► **FIGURE 10-15** Concurrent platelet aggregation and clot formation. Exposed collagen at the site of vessel damage simultaneously initiates platelet aggregation and the clotting cascade. These two haemostatic mechanisms positively reinforce each other as they seal the damaged vessel.

The intrinsic and extrinsic mechanisms usually operate simultaneously. When tissue injury involves rupture of vessels, the intrinsic mechanism stops blood in the injured vessel, whereas the extrinsic mechanism clots blood that escaped into the tissue before the vessel was sealed off. Typically, clots are fully formed in three to six minutes.

CLOT RETRACTION

Once a clot is formed, contraction of the platelets trapped within the clot shrinks the fibrin mesh, pulling the edges of the damaged vessel closer together. During **clot retraction**, fluid is squeezed from the clot. This fluid, called **serum**, is essentially plasma minus the fibrinogen and other clotting precursors that have been removed during the clotting process.

AMPLIFICATION DURING CLOTTING PROCESS

Although a clotting process that involves so many steps may seem inefficient, its advantage is the amplification accomplished during many of the steps. One molecule of an activated factor can activate perhaps a hundred molecules of the next factor in the sequence, each of which can activate many more molecules of the next factor, and so on. In this way, large numbers of the final factors involved in clotting are rapidly activated as a result of the initial activation of only a few molecules in the beginning step of the sequence.

How then is the clotting process, once initiated, confined to the site of vessel injury? If the activated clotting factors were allowed to circulate, they would induce inappropriate widespread clotting that would plug up vessels throughout the body. Fortunately, after participating in the local clotting process, the massive number of factors activated in the vicinity of vessel injury is rapidly inactivated by enzymes and other factors present in the plasma or tissue.

Fibrinolytic plasmin

A clot is not meant to be a permanent solution to vessel injury. It is a transient device to stop bleeding until the vessel can be repaired.

VESSEL REPAIR

The aggregated platelets secrete a chemical that helps promote the invasion of fibroblasts (fibre formers) from the surrounding connective tissue into the wounded area of the vessel. Fibroblasts form a scar at the vessel defect.

CLOT DISSOLUTION

Simultaneous with the healing process, the clot, which is no longer needed to prevent haemorrhage, is slowly dissolved by a fibrinolytic (fibrin-splitting) enzyme called **plasmin**. If clots were not removed after they performed their haemostatic function, the vessels, especially the small ones that endure tiny ruptures on a regular basis, would eventually become obstructed by clots.

Plasmin, like the clotting factors, is a plasma protein produced by the liver and present in the blood in an inactive precursor form, **plasminogen**. Plasmin is activated in a fast cascade of reactions involving many factors, among them factor XII (Hageman factor), which also triggers the chain reaction leading

► **FIGURE 10-16** Role of factor XII in clot formation and dissolution.

Activation of factor XII (Hageman factor) simultaneously initiates a fast cascade of reactions that results in clot formation and a fast cascade of reactions that results in plasmin activation. Plasmin, which is trapped in the clot, subsequently slowly dissolves the clot. This action removes the clot when it is no longer needed after the vessel has been repaired.

to clot formation (► Figure 10-16). When a clot is rapidly being formed, activated plasmin becomes trapped in the clot and later dissolves it by slowly breaking down the fibrin meshwork.

Phagocytic white blood cells gradually remove the products of clot dissolution. Following an injury, you have likely observed the black-and-blue marks of bruised skin. The coloration results from the slow removal of the deoxygenated clotted blood that escaped into the tissue layers of your skin. This blood is eventually cleared by plasmin action, followed by the phagocytic cleanup crew.

PREVENTING INAPPROPRIATE CLOT FORMATION

In addition to removing clots that are no longer needed, plasmin functions continually to prevent clots from forming inappropriately. Throughout the vasculature, small amounts of fibrinogen are constantly converted into fibrin, triggered by unknown mechanisms. Clots do not develop, however, because plasmin, activated by **tissue plasminogen activator (tPA)**, quickly gets rid of the fibrin from the tissues, especially the lungs. Normally, the low level of fibrin formation is counterbalanced by a low level of fibrinolytic activity, so inappropriate clotting does not occur. Only when a vessel is damaged do additional factors precipitate the explosive chain reaction that leads to more extensive fibrin formation and results in local clotting at the site of injury.

 Genetically engineered tPA and other similar chemicals that trigger clot dissolution are frequently used to limit damage to cardiac muscle during heart attacks. Administering a clot-busting drug within the first hours after a clot has blocked a coronary (heart) vessel often dissolves the clot in time to restore blood flow to the cardiac muscle that is supplied by the blocked vessel before the muscle dies of oxygen deprivation. In recent years, tPA and related drugs have also been used successfully to promptly dissolve a stroke-causing clot within a cerebral

(brain) blood vessel, thereby minimizing loss of irreplaceable brain tissue after a stroke (p. 114).

Inappropriate clotting

 Despite protective measures, clots occasionally form in intact vessels. Abnormal or excessive clot formation within blood vessels—what has been dubbed “haemostasis in the wrong place”—can compromise blood flow to vital organs. The body’s clotting and anticlotting systems normally function in a check-and-balance manner. Acting in concert, they permit prompt formation of “good” blood clots, thus minimizing blood loss from damaged vessels, while preventing “bad” clots from forming and blocking blood flow in intact vessels. An abnormal intravascular clot attached to a vessel wall is known as a **thrombus**, and a freely floating clot is called **embolus**. An enlarging thrombus narrows and can eventually completely occlude the vessel in which it forms. By entering and completely plugging a smaller vessel, a circulating embolus can suddenly block blood flow (see Figure 8-29).

Several factors, acting independently or simultaneously, can cause **thromboembolism**: (1) Roughened vessel surfaces associated with atherosclerosis can lead to thrombus formation (p. 378). (2) Imbalances in the clotting–anticlotting systems can trigger clot formation. (3) Slow-moving blood is more apt to clot, probably because small quantities of fibrin accumulate in the stagnant blood, for example, in blood pooled in varicose leg veins (p. 418). (4) Widespread clotting is occasionally triggered by the release of tissue thromboplastin into the blood from large amounts of traumatized tissue. Similar widespread clotting can occur in **septicaemic shock**, in which bacteria or their toxins initiate the clotting cascade.

Haemophilia

 In contrast to inappropriate clot formation in intact vessels, the opposite haemostatic disorder is the failure of clots to form promptly in injured vessels, resulting in life-threatening haemorrhage even from relatively mild traumas. The most common cause of excessive bleeding is **haemophilia**, which is caused by a deficiency of one of the factors in the clotting cascade. Although a deficiency of any of the clotting factors could block the clotting process, 80 percent of all haemophiliacs lack the genetic ability to synthesize factor VIII.

People with a platelet deficiency, in contrast to the more profuse bleeding that accompanies defects in the clotting mechanism, continuously develop hundreds of small, confined haemorrhagic areas throughout the body tissues as blood leaks from tiny breaks in the small blood vessels before coagulation takes place. Platelets normally are the primary sealers of these ever-occurring minute ruptures. In the skin of a platelet-deficient person, the diffuse capillary haemorrhages are visible as small, purplish blotches, giving rise to the term **thrombocytopenia purpura** (the purple of thrombocyte deficiency) for this condition. (Recall that *thrombocyte* is another name for platelet.)

Vitamin K deficiency can also cause a bleeding tendency. Vitamin K, commonly known as the blood-clotting vitamin,

is essential for normal clot formation. Researchers recently figured out vitamin K's role in the clotting process. In a complex sequence of biochemical events, vitamin K combines with oxygen, releasing free energy that is ultimately used in the activation processes of the clotting cascade.

Chapter in Perspective: Focus on Homeostasis

Blood contributes to homeostasis in a variety of ways. First, the composition of interstitial fluid—the true internal environment that surrounds and directly exchanges materials with the cells—depends on the composition of blood plasma. Because of the thorough exchange that occurs between the interstitial and vascular compartments, interstitial fluid has the same composition as plasma with the exception of plasma proteins, which cannot escape through the capillary walls. Thus, blood serves as the vehicle for rapid, long-distance, mass transport of materials to and from the cells, and interstitial fluid serves as the go-between.

Homeostasis depends on the blood carrying materials such as oxygen and nutrients to the cells as rapidly as the cells consume these supplies, and carrying materials such as metabolic wastes away from the cells as rapidly as the cells produce these products. It also depends on the blood carrying hormonal messengers from their site of production to their distant site of action. Once a substance enters the blood, it can be transported throughout the body within seconds, whereas diffusion of the substance over long distances in a large multicellular organism, such as a human, would take months to years—a situation incompatible with life. Diffusion can, however, effectively accomplish short local exchanges of materials between blood and surrounding cells through the intervening interstitial fluid.

Blood has special transport capabilities that enable it to move its cargo efficiently throughout the body. For example, life-sustaining oxygen is poorly soluble in water, but blood is equipped with O_2 -carrying specialists, the erythrocytes (red blood cells), which are stuffed full of

Check Your Understanding 10.4

1. Describe how a platelet plug forms at the site of a vessel defect.
2. Draw a flow diagram showing the intrinsic and extrinsic pathways of the clotting cascade.

haemoglobin, a complex molecule that transports oxygen. Likewise, homeostatically important water-insoluble hormonal messengers are shuttled in the blood by plasma protein carriers.

Specific components of the blood perform the following additional homeostatic activities that are unrelated to blood's transport function:

- Blood helps maintain the proper pH in the internal environment by buffering changes in the body's acid–base load.
- Blood helps maintain body temperature by absorbing heat produced by heat-generating tissues such as contracting skeletal muscles and distributing it throughout the body. Excess heat is carried by the blood to the body surface for elimination to the external environment.
- Electrolytes in the plasma are important in membrane excitability, which is critical for nerve and muscle function.
- Electrolytes in the plasma are important in osmotic distribution of fluid between the extracellular and intracellular fluid. Plasma proteins play a critical role in distributing extracellular fluid between the plasma and interstitial fluid.
- Through their haemostatic functions, the platelets and clotting factors minimize the loss of life-sustaining blood after vessel injury.
- The leukocytes (white blood cells), their secretory products, and certain types of plasma proteins, such as antibodies, constitute the immune defence system. This system defends the body against invading disease-causing agents, destroys cancer cells, and paves the way for wound healing and tissue repair by clearing away debris from dead or injured cells. These actions indirectly contribute to homeostasis by helping the organs that directly maintain homeostasis stay healthy. We could not survive beyond early infancy were it not for the body's defence mechanisms.

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-45)

1. Blood can absorb metabolic heat while undergoing only small changes in temperature. (*True or false?*)
2. Haemoglobin can carry only oxygen. (*True or false?*)
3. Erythrocytes, leukocytes, and platelets all originate from the same undifferentiated stem cells. (*True or false?*)
4. Erythrocytes are unable to use the oxygen they contain for their own ATP formation. (*True or false?*)
5. White blood cells spend the majority of their time in the blood. (*True or false?*)
6. Which type of leukocyte is produced primarily in lymphoid tissue? _____
7. Most clotting factors are synthesized by the _____.
8. Which of the following is NOT a function of plasma proteins?
 - a. facilitating retention of fluid in the blood vessels
 - b. playing an important role in blood clotting
 - c. transporting water-insoluble substances in the blood
 - d. transporting oxygen in the blood
 - e. serving as antibodies
 - f. contributing to the buffering capacity of the blood
9. Which of the following is NOT directly triggered by exposed collagen in an injured vessel?
 - a. initial vascular spasm
 - b. platelet aggregation
 - c. activation of the clotting cascade
 - d. activation of plasminogen

10. Match the following (an answer may be used more than once):

- | | |
|--|--------------------------------------|
| ___ 1. causes platelets to aggregate in feedback fashion | ___ 3. fibrinolytic enzyme |
| ___ 2. activates prothrombin | ___ 4. inhibits platelet aggregation |

- | | |
|---|------------------|
| ___ 5. first factor activated in intrinsic clotting pathway | (a) prostacyclin |
| ___ 6. forms meshwork of the clot | (b) plasmin |
| ___ 7. stabilizes the clot | (c) ADP |
| ___ 8. activates fibrinogen | (d) fibrin |
| ___ 9. activated by tissue thromboplastin | (e) thrombin |
| | (f) factor X |
| | (g) factor XII |
| | (h) factor XIII |

11. Match the following blood abnormalities with their causes:

- | | |
|---|-----------------------------|
| ___ 1. deficiency of intrinsic factor | (a) haemolytic anaemia |
| ___ 2. insufficient amount of iron to synthesize adequate haemoglobin | (b) aplastic anaemia |
| ___ 3. destruction of bone marrow | (c) nutritional anaemia |
| ___ 4. abnormal loss of blood | (d) haemorrhagic anaemia |
| ___ 5. tumour-like condition of bone marrow | (e) pernicious anaemia |
| ___ 6. inadequate erythropoietin secretion | (f) renal anaemia |
| ___ 7. excessive rupture of circulating erythrocytes | (g) primary polycythaemia |
| ___ 8. associated with living at high altitudes | (h) secondary polycythaemia |

Written Questions

1. What is the average blood volume in women and in men?
2. What is the normal percentage of blood occupied by erythrocytes and by plasma? What is the haematocrit? What is the buffy coat?
3. What is the composition of plasma?
4. List the three major groups of plasma proteins, and state their functions.
5. Describe the structure and functions of erythrocytes.
6. Why can erythrocytes survive for only about 120 days?
7. Describe the process and control of erythropoiesis.

8. Compare the structures, functions, and lifespans of the five types of leukocytes.
9. Discuss the derivation of platelets.
10. Describe the three steps of haemostasis, including a comparison of the intrinsic and extrinsic pathways by which the clotting cascade is triggered.
11. Compare plasma and serum.
12. What normally prevents inappropriate clotting in vessels?

Quantitative Exercises (Solutions in Appendix E, p. A-45)

1. The normal concentration of haemoglobin in blood (as measured clinically) is 15 g/100 mL of blood.
 - a. Given that 1 mole of haemoglobin weighs 66 000 g, what is the concentration of haemoglobin in millimoles (mM)?
 - b. Each haemoglobin molecule can bind four molecules of oxygen. What is the concentration of oxygen bound to haemoglobin at maximal saturation (in mM)?
 - c. Given that 1 mole of an ideal gas occupies 22.4 L, what is the maximal carrying capacity of normal blood for oxygen (usually expressed in mL of O₂/litre of blood)?

2. Assume that the blood sample in ▶ Figure 10-5b, is from a patient with haemorrhagic anaemia. Given a normal blood volume of 5 L, a normal red blood cell concentration of 5 billion/mL, and an RBC production rate of 3 million cells/second, how long will it take the body to return the haematocrit to normal?
3. Note that in the blood sample (in Figure 10-5c) from a patient with polycythaemia, the haematocrit has increased to 70 percent. An increased haematocrit increases blood viscosity, which in turn increases total peripheral resistance and increases the workload on the heart. The effect of haematocrit (h) on relative blood viscosity (ν , viscosity relative to that of water) is given approximately by the following equation:

$$\nu = 1.5 \times \exp(2h)$$

Note that in this equation, h is the haematocrit as a fraction, not a percentage. Given a normal haematocrit of 0.40, what percent increase in viscosity would result from the polycythaemia in Figure 10-5c? What percentage change would this cause in total peripheral resistance?

POINTS TO PONDER

(Explanations in Appendix E, p. A-46)

1. A person has a haematocrit of 62. Can you conclude from this finding that the person has polycythaemia? Explain.
2. There are different forms of haemoglobin. *Haemoglobin A* is normal adult haemoglobin. The abnormal form *haemoglobin S* causes RBCs to warp into fragile, sickle-shaped cells. Fetal RBCs contain *haemoglobin F*, the production of which stops soon after birth. Now researchers are trying to goad the genes that direct haemoglobin *F* synthesis back into action as a means of treating sickle cell anaemia. Explain how turning on these fetal genes could be a useful remedy. (Indeed, the first effective drug therapy recently approved for treating sickle cell anaemia, *hydroxyurea*, acts on the bone marrow to boost production of fetal haemoglobin.)
3. Low on the list of popular animals are vampire bats, leeches, and ticks, yet these animals may someday indirectly save your life. Scientists are currently examining the “saliva” of these blood-sucking creatures in search of new

chemicals that might limit cardiac muscle damage in heart attack victims. What do you suspect is the nature of these sought-after chemicals?

4. *Porphyria* is a genetic disorder that shows up in about 1 in every 25 000 individuals. Affected individuals lack certain enzymes that are part of a metabolic pathway leading to formation of heme, which is the iron-containing group of haemoglobin. An accumulation of porphyrins, which are intermediates of the pathway, causes a variety of symptoms, especially after exposure to sunlight. Lesions and scars form on the skin. Hair grows thickly on the face and hands. As gums retreat from teeth, the elongated canine teeth take on a fanglike appearance. Symptoms worsen on exposure to a variety of substances, including garlic and alcohol. Affected individuals avoid sunlight and aggravating substances and get injections of heme from normal red blood cells. If you are familiar with vampire stories, which date from the Middle Ages or earlier, speculate on how they may have evolved among superstitious folk who did not have medical knowledge of porphyria.

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-46)

Linda P. has just been diagnosed as having pneumonia. Her white blood cell count is 7200/mm³, and 67 percent of the white blood cells are neutrophils. It will take several days to obtain a definitive answer as to the causative agent by culturing

a sample of discharges from her respiratory system. Based on the WBC count, do you think that Linda should be given antibiotics immediately, long before the causative agent is actually known? Are antibiotics likely to combat her infection?

Cells make up body systems

Homeostasis

The immune system defends against foreign invaders and cancer cells and paves the way for tissue repair. The integumentary system (skin) prevents the entrance of external agents and the loss of internal fluid by serving as a protective barrier between the external environment and the remainder of the body.

Homeostasis is essential for survival of cells

© David M. Phillips/Science Source

Macrophage ingesting pseudomonas

Humans constantly come into contact with external agents that could be harmful if they entered the body. The most serious are disease-causing microorganisms.

If bacteria or viruses do gain entry, the body is equipped with a complex, multifaceted, internal defence system—the immune system—that provides continual protection against invasion by foreign agents. Furthermore, body surfaces exposed to the

external environment, such as the integumentary system (skin), serve as a first line of defence to resist penetration by foreign microorganisms. The immune system also protects against cancer and paves the way for repair of damaged tissues.

The immune system indirectly contributes to homeostasis by helping maintain the health of organs that directly contribute to homeostasis.

Clinical Connections

Caitlin is a 14-year-old-girl who has had a history of seasonal hay fever. For the past day she has complained about the symptoms being worse than usual.

During the night she woke as she was having problems drawing in breath. Gasping and wheezing she alerted her parents, who took her to the hospital where she was immediately treated for what appeared to be an asthma attack. Her blood work showed an elevated white cell count with normal haemoglobin, and there were eosinophils in her sputum. Her chest X-ray was normal. Once her breathing was under control she was discharged with asthma medication and a list of follow-up tests to be done. A pulmonary function test found that she had an obstructed airway, which was reversed with the β_2 -adrenergic stimulant normally given for asthma. At an allergy specialist, she had several positive skin tests. Ultimately, her diagnosis was changed to allergic asthma.

11.1 | Introduction

Immunity is the body's ability to resist or eliminate potentially harmful foreign materials or abnormal cells. The following activities are attributable to the **immune system**, an internal defence system that plays a key role in recognizing and either destroying or neutralizing materials within the body that are foreign to the **body's own cells**:

1. Defending against invading pathogens (microorganisms, e.g., bacteria and viruses)
2. Removing worn-out cells damaged by trauma or disease, and facilitating wound healing and tissue repair
3. Identifying and destroying abnormal or mutant cells that originated in the body, a task (*immune surveillance*) that is the chief internal-defence mechanism against cancer
4. Mounting inappropriate immune responses that lead either to *allergies*, which occur when the body turns against a normally harmless environmental chemical entity, or to *autoimmune diseases*, which happen when the defence system erroneously produces antibodies against a particular type of the body's own cells

Many actions we undertake throughout our daily lives influence the function of our immune systems and thus our immunity. However, only one action in particular has been shown to have a profound effect on the short-term (acute) and long-term (chronic) functioning of our immune system: exercise.

Pathogenic bacteria and viruses

The primary foreign enemies that the immune system defends against are bacteria and viruses. **Bacteria** (which are large) are non-nucleated, single-celled microorganisms self-equipped with all the machinery essential for their own survival and reproduction. Pathogenic bacteria that invade the body cause tissue damage and produce disease largely by releasing enzymes or toxins that physically injure or functionally disrupt affected cells and organs. The disease-producing power of a pathogen is known as its **virulence**.

In contrast to bacteria, **viruses** (which are small) are not self-sustaining cellular entities. They consist only of nucleic acids (genetic material—DNA or RNA) enclosed by a protein coat. Because they lack cellular machinery for energy production and protein synthesis, viruses cannot carry out metabolism and reproduce unless they invade a **host cell** (a body cell of the infected individual) and take over the cell's biochemical facilities for their own uses. Not only do viruses sap the host cell's energy resources, but the viral nucleic acids also direct the host cell to synthesize proteins needed for viral replication.

When a virus becomes incorporated into a host cell, the body's own defence mechanisms may destroy the cell because they no longer recognize it as a "self" cell (they see the cell as foreign). Other ways in which viruses can lead to cell damage or death are by depleting essential cell components, dictating that the cell produce substances toxic to the cell, or transforming the cell into a cancer cell. Let's now take a brief look at the pathology of a virus.

Some common viruses are SARS (severe acute respiratory syndrome), H1N1 (influenza A virus), and avian (bird) flu. The

H1N1 virus was responsible for the 2009 pandemic (epidemic of wide geography) that started in Mexico, while the avian flu was caused by a virus adapted to birds. Each is a viral infection that presents its own unique challenge to immunologists (those that study immunology) and virologists (those that study viruses).

SARS VIRUS

Here is a closer look at the SARS virus: it is caused by the coronavirus (common cold family) and spread by airborne respiratory secretions (coughing or sneezing infected droplets). SARS is contracted (caught) by breathing in or touching the respiratory secretions of an infected person. The virus may live on hands, tissues, and surfaces (e.g., door knob) for six hours in wet-droplet form and three hours in dried-droplet form. The virus has even been found to live for four days in feces, and might live for months when the temperature is below freezing. Many viruses are spread over large distances via world travel. If we take the first case of SARS as an example, it was spread by a traveller; a middle-age businessman travelling from China to Vietnam via Hong Kong. The businessman later died as a result of the virus. Outside of Asia, SARS had the greatest impact on Toronto, Canada, where over 25 000 persons were placed in quarantine. In total, 400 Canadians became ill with the disease and 44 died. The total death rate in 2003 was about 15 percent of cases, but in cases of persons over 65 years of age the death rate was about 50 percent.

Symptoms present in 2–10 days following contact with the virus, but there are cases outside this range. Persons with SARS symptoms are contagious, but a person may be contagious before symptoms present or after they subside. Typical symptoms include fever ($\geq 38.0^{\circ}\text{C}$) and cough, difficulty breathing, or other respiratory symptoms. Treatment is commonly antibiotics, antiviral medications, high doses of steroids, and oxygen or mechanical ventilation. To reduce the risk of contracting SARS or other viruses, people should cover their mouth and nose in their arm when sneezing or coughing, and not share food, beverages, or utensils with others. Commonly touched surfaces should be cleaned with disinfectant. Although SARS is not a major health risk at this time, taking such basic precautions reduce the risk of infection and outbreaks.

BODY DEFENCES

When considering how the body defends against foreign pathogens, we can broadly classify the mechanisms as either **external defences** (the integumentary system) or **internal defences** (the immune system). We begin our discussion of body defences with an overview of the **integumentary system**. This is followed by a detailed description of how the immune system functions and its role in homeostasis.

11.2 | External Defences

The **skin (integument)**, which is the largest organ of the body, not only serves as a mechanical barrier between the external environment and the underlying tissues but also is dynamically involved in defence mechanisms and other important functions. The skin consists of two layers, an outer *epidermis* and an inner *dermis* (➤ Figure 11-1).

► **FIGURE 11-1 Anatomy of the skin.** The skin consists of two layers, a keratinized outer epidermis and a richly vascularized inner connective tissue dermis. Special infoldings of the epidermis form the sweat glands, sebaceous glands, and hair follicles. The epidermis contains four types of cells: keratinocytes, melanocytes, Langerhans cells, and Granstein cells. The skin is anchored to underlying muscle or bone by the hypodermis, a loose, fat-containing layer of connective tissue.

Epidermis

The **epidermis** consists of numerous layers of epithelial cells. On average, the epidermis replaces itself about every two and a half months. The inner epidermal layers are composed of cube-shaped cells that are living and rapidly dividing, whereas the cells in the outer layers are dead and flattened. The epidermis has no direct blood supply. Its cells are nourished only by diffusion of nutrients from a rich vascular network in the underlying dermis. The newly forming cells in the inner layers constantly push the older cells closer to the surface, farther and farther from their nutrient supply. This, coupled with the fact that the outer layers are continuously subjected to pressure and “wear and tear,” causes these older cells to die and become flattened. Epidermal cells are riveted tightly together by desmosomes (p. 34), which interconnect with intracellular keratin filaments (p. 34) to form a strong, cohesive covering. During maturation of a keratin-producing cell, keratin filaments progressively accumulate and cross-link with one another within the cytosol. As the outer cells die, this fibrous keratin core remains, forming flattened, hardened scales that provide a tough, protective, **keratinized layer**. As the scales of the outermost keratinized

layer slough or flake off through abrasion, they are continuously replaced by means of cell division in the deeper epidermal layers. The rate of cell division, and consequently the thickness of this keratinized layer, varies in different regions of the body. It is thickest in the areas where the skin is subjected to the most pressure, such as the bottom of the feet. The keratinized layer is airtight, fairly waterproof, and impervious to most substances. It resists anything passing in either direction between the body and external environment. For example, it minimizes loss of water and other vital constituents from the body and prevents most foreign material from penetrating into the body.

Clinical Note This protective layer’s value in holding in body fluids becomes obvious after severe burns. Bacterial infections can occur in the unprotected underlying tissue, but even more serious are the systemic consequences of loss of body water and plasma proteins, which escape from the exposed, burned surface. The resulting circulatory disturbances can be life threatening.

Likewise, the skin barrier impedes passage into the body of most materials that come into contact with the body surface, including bacteria and toxic chemicals. In many instances, the skin modifies compounds that come into contact with it. For example, epidermal enzymes can convert many potential carcinogens into harmless compounds. Some materials, however, especially lipid-soluble substances, can penetrate intact skin through the lipid bilayers of the plasma membranes of the epidermal cells. Drugs that can be absorbed by the skin, such as nicotine or estrogen, are sometimes used in the form of a cutaneous patch impregnated with the drug.

Dermis

Under the epidermis is the **dermis**, a connective tissue layer that contains many elastin fibres (for stretch) and collagen fibres (for strength), as well as an abundance of blood vessels and specialized nerve endings. The dermal blood vessels not only supply both the dermis and epidermis but also play a major role in temperature regulation. The calibre of these vessels, and hence the volume of blood flowing through them, is subject to control to vary the amount of heat exchange between these skin surface vessels and the external environment (Chapter 16). Receptors

at the peripheral endings of afferent nerve fibres in the dermis detect pressure, temperature, pain, and other somatosensory input. Efferent nerve endings in the dermis control blood vessel calibre, hair erection, and secretion by the skin's exocrine glands.

Skin's exocrine glands and hair follicles

Special infoldings of the epidermis into the underlying dermis form the skin's exocrine glands—the sweat glands and sebaceous glands—as well as the hair follicles. **Sweat glands**, which are distributed over most of the body, release a dilute salt solution through small openings, the sweat pores, onto the skin surface. Evaporation of this sweat cools the skin and is important in regulating temperature.

The amount of sweat produced is subject to regulation and depends on the environmental temperature, the amount of heat-generating skeletal muscle activity, and various emotional factors (e.g., a person often sweats when nervous). A special type of sweat gland located in the axilla (armpit) and pubic region produces a protein-rich sweat that supports the growth of surface bacteria, which give rise to a characteristic odour. In contrast, most sweat, as well as the secretions from the sebaceous glands, contains chemicals that are generally highly toxic to bacteria.

The cells of the **sebaceous glands** produce **sebum**, an oily secretion released into adjacent hair follicles. From there, sebum flows to the skin surface, oiling both the hairs and the outer keratinized layers of the skin, which helps to waterproof them and prevent them from drying and cracking. Chapped hands or lips indicate insufficient protection by sebum. The sebaceous glands are particularly active during adolescence, causing the oily skin common among teenagers.

Each **hair follicle** is lined with special keratin-producing cells, which secrete keratin and other proteins that form the hair shaft. Hairs increase the sensitivity of the skin's surface to tactile (touch) stimuli. In some other species, this function is more finely tuned. For example, the whiskers on a cat are exquisitely sensitive in this regard. An even more important role of hair in hairy species is heat conservation, a function that's not significant in humans. Like hair, the **nails** are another special keratinized product derived from living epidermal structures, the nail beds.

Hypodermis

The skin is anchored to the underlying tissue (muscle or bone) by the **hypodermis** (*hypo* means “below”), also known as **subcutaneous tissue** (*sub* means “under”; *cutaneous* means “skin”), a loose layer of connective tissue. Most fat cells are housed within the hypodermis. These fat deposits throughout the body are collectively referred to as **adipose tissue**.

Specialized cells

The epidermis contains four distinct resident cell types—**melanocytes**, **keratinocytes**, **Langerhans cells**, and **Granstein cells**—plus transient T lymphocytes that are scattered throughout the epidermis and dermis. Each of these resident cell types performs specialized functions.

MELANOCYTES

Melanocytes produce the pigment melanin, which they disperse to surrounding skin cells. The amount and type of melanin, which can vary among black, brown, yellow, and red pigments, are responsible for the differences in human skin coloration. Fair-skinned people have about the same number of melanocytes as dark-skinned people; the difference in skin colour depends on the amount of melanin produced by each melanocyte. Melanin is produced through complex biochemical pathways in which the melanocyte enzyme *tyrosinase* plays a key role. Most people, regardless of skin colour, have enough tyrosinase that, if fully functional, could result in enough melanin to make their skin very black. In those with lighter skin, however, two genetic factors prevent this melanocyte enzyme from functioning at full capacity: (1) much of the tyrosinase produced is in an inactive form, and (2) various inhibitors that block tyrosinase action are produced. As a result, less melanin is produced.

In addition to hereditary determination of melanin content, the amount of this pigment can be increased transiently in response to exposure to ultraviolet (UV) light rays from the sun. This additional melanin provides the protective function of absorbing harmful UV rays—and gives the appearance of a suntan. For more information, see Why It Matters.

KERATINOCYTES

The most abundant epidermal cells are the **keratinocytes**. As they die, they form the outer protective keratinized layer. They also generate hair and nails. A surprising, recently discovered function is that keratinocytes are also important immunologically. They secrete interleukin 1 (a product also secreted by macrophages), which influences the maturation of T cells that tend to localize in the skin. Interestingly, the epithelial cells of the thymus have been shown to have anatomic, molecular, and functional similarities to those of the skin. This suggests keratinocytes have an influence on some post-thymic steps in T-cell maturation that take place in the skin.

OTHER IMMUNE CELLS OF THE SKIN

As well as keratinocytes, the Langerhans cells and the Granstein cells are the two other epidermal cell types that play a role in immunity. **Langerhans cells**, which migrate to the skin from the bone marrow, are dendritic cells that serve as antigen-presenting cells. Thus, the skin not only is a mechanical barrier but also alerts lymphocytes if the barrier is breached by invading microorganisms. Langerhans cells present antigen to helper T cells, facilitating their responsiveness to skin-associated antigens. In contrast, **Granstein cells** seem to act to hinder skin-activated immune responses. These cells are the most recently discovered and least understood of the skin's immune cells. Significantly, Langerhans cells are more susceptible to damage by UV radiation (as from the sun) than Granstein cells are. Losing Langerhans cells as a result of exposure to UV radiation can detrimentally lead to a predominant suppressor signal rather than the normally dominant helper signal, leaving the skin more vulnerable to microbial invasion and cancer cells.

The various epidermal components of the immune system are collectively termed **skin-associated lymphoid tissue (SALT)**.

The two major forms of ultraviolet (UV) light that are of concern are called UVA and UVB, both of which are of major health concern. Both UVA and UVB are capable of penetrating the skin. The longer wavelength UVA rays can penetrate deeper into the skin, but are potentially less reactive. In contrast, the shorter wavelength UVB rays cannot penetrate as deeply, but are more reactive. When melanin is present in the skin, it can act to neutralize the effects of these harmful rays. However, when the protective effects of melanin are overwhelmed, UV light can have many affects, ranging from sunburn to the development of skin cancer.

One of UV light's most deleterious actions is to damage DNA, which can be done directly or indirectly. Direct DNA damage occurs when UVB light is absorbed by DNA and disrupts the structure of the strands. Such

damages are thought to underlie sunburn as well as lead to some types of cancers. The impact of indirect DNA damage is harder to assess. It is caused by UV light interacting with molecules within the skin to form reactive oxygen species, which in turn can directly damage nearby DNA as well as travel within the body to have deleterious effects elsewhere.

Melanin itself cannot always protect your skin from damage. Fortunately, the development of sunscreens and sunblocks can pick up where your natural defences drop off. Sunscreen works by absorbing the UV rays, but some of these rays still penetrate. Sunblocks are more effective and work by reflecting or scattering the UV rays so that they do not penetrate into the skin. For maximum protection, make sure you choose a lotion that contains both a sunscreen and a sunblock.

Recent research suggests that the skin probably plays an even more elaborate role in adaptive immune defence than described here. This is appropriate, because the skin serves as a major interface with the external environment.

VITAMIN D SYNTHESIS BY THE SKIN

The epidermis also synthesizes vitamin D in the presence of sunlight. The cell type that produces vitamin D is undetermined. Vitamin D, which is derived from a precursor molecule closely related to cholesterol, promotes the absorption of calcium from the digestive tract into the blood (Chapter 15). Dietary supplements of vitamin D are usually required because typically the skin is not exposed to sufficient sunlight to produce adequate amounts of this essential chemical.

Protective measures

The human body's defence system guards against entry of potential pathogens not only through the outer surface of the body but also through the internal cavities that communicate directly with the external environment—namely, the digestive system, the genitourinary system, and the respiratory system. These systems use various tactics to destroy microorganisms entering through these routes.

DEFENCES OF THE DIGESTIVE SYSTEM

Saliva secreted into the mouth at the entrance to the digestive system contains an enzyme that lyses certain ingested bacteria. The so-called friendly bacteria that live on the back of the tongue convert food-derived nitrate into nitrite, which is swallowed. Acidification of nitrite on reaching the highly acidic stomach generates nitric oxide, which is toxic to a variety of microorganisms. Furthermore, many of the surviving bacteria that are swallowed are killed directly by the strongly acidic gastric juice in the stomach. Farther down the tract, the intestinal lining is endowed with gut-associated lymphoid tissue. These defensive

mechanisms are not 100 percent effective, however. Some bacteria do manage to survive and reach the large intestine (the last portion of the digestive tract), where they continue to flourish. Surprisingly, this normal microbial population provides a natural barrier against infection within the lower intestine. These harmless resident microbes competitively suppress the growth of potential pathogens that have managed to escape the antimicrobial measures of earlier parts of the digestive tract.

 On occasion, orally administered antibiotic therapy against an infection elsewhere within the body may actually induce an intestinal infection. By knocking out some of the normal intestinal bacteria, an antibiotic may permit an antibiotic-resistant pathogenic species to overgrow in the intestine.

DEFENCES OF THE GENITOURINARY SYSTEMS

Within the genitourinary (reproductive and urinary) system, would-be invaders encounter hostile conditions in the acidic urine and acidic vaginal secretions. The genitourinary organs also produce a sticky mucus, which, like flypaper, entraps small invading particles. Subsequently, the particles are either engulfed by phagocytes or are swept out as the organ empties (e.g., flushed out with urine flow).

DEFENCES OF THE RESPIRATORY SYSTEM

The respiratory system is likewise equipped with several important defence mechanisms against inhaled particulate matter. The respiratory system is the largest surface of the body that comes into direct contact with the increasingly polluted external environment. The surface area of the respiratory system exposed to the air is 30 times that of the skin. Larger airborne particles are filtered out of the inhaled air by hairs at the entrance of the nasal passages. Lymphoid tissues, the *tonsils* and *adenoids*, provide immunological protection against inhaled pathogens near the beginning of the respiratory system. Farther down the respiratory airways, millions of tiny hairlike projections known as *cilia* constantly beat

in an outward direction. The respiratory airways are coated with a layer of thick, sticky mucus secreted by epithelial cells within the airway lining. This mucous sheet, laden with any inspired particulate debris (such as dust) that adheres to it, is constantly moved upward to the throat by ciliary action. This movement of mucus is known as the **mucociliary escalator**. The dirty mucus is either expectorated (spit out) or typically swallowed without the person being aware of it; any indigestible foreign particulate matter is later eliminated in the feces. As well as keeping the lungs clean, this mechanism is an important defence against bacterial infection, because many bacteria enter the body on dust particles. Also contributing to defence against respiratory infections are antibodies secreted in the mucus. In addition, an abundance of phagocytic specialists called the **alveolar macrophages** scavenge within the air sacs (alveoli) of the lungs. Further respiratory defences include coughs and sneezes. These commonly experienced reflex mechanisms involve forceful outward expulsion of material in an attempt to remove irritants from the trachea (*coughs*) or nose (*sneezes*).

Clinical Connections

Caitlin had suffered from hay fever for years and was used to the coughing and sneezing that occurs in an attempt to remove the irritant. However, her condition had progressed to allergic asthma, a condition in which the mucus-secreting cells become larger and secrete greater quantities of mucus, which in turn triggers more coughing. Although asthma is commonly associated with the characteristic wheezing in the airways, the most common symptom is periodic, persistent coughing.

Cigarette smoking suppresses these normal respiratory defences. The smoke from a single cigarette can paralyze the cilia for several hours, and repeated exposure eventually leads to ciliary destruction. Failure of ciliary activity to sweep out a constant stream of particulate-laden mucus enables inhaled carcinogens to remain in contact with the respiratory airways for prolonged periods. Furthermore, cigarette smoke incapacitates alveolar macrophages. Not only do particulates in cigarette smoke overwhelm the macrophages but certain components of cigarette smoke have a direct toxic effect on the macrophages, reducing their ability to engulf foreign material. In addition, noxious agents in tobacco smoke irritate the mucous linings of the respiratory tract, resulting in excess mucus production, which may partially obstruct the airways. “Smoker’s cough” is an attempt to dislodge this excess stationary mucus. These and other direct toxic effects on lung tissue lead to the increased incidence of lung cancer and chronic respiratory diseases associated

with cigarette smoking. Air pollutants include some of the same substances found in cigarette smoke and can similarly affect the respiratory system.

11.3 Internal Defences

Leukocytes

Leukocytes (white blood cells, or WBCs) and their derivatives, along with a variety of plasma proteins, are responsible for the different immune defence strategies.

LYMPHOCYTE FUNCTIONS

As a brief review, the functions of the five types of leukocytes are as follows (pp. 446–447):

1. Neutrophils are highly mobile phagocytic specialists that engulf and destroy unwanted materials.
2. Eosinophils secrete chemicals that destroy parasitic worms and are involved in allergic reactions.
3. Basophils release histamine and heparin and also are involved in allergic reactions.
4. Monocytes are transformed into **macrophages**, which are large, tissue-bound phagocytic specialists.
5. Lymphocytes are of two types.
 - a. B lymphocytes (B cells) are transformed into plasma cells, which secrete antibodies that indirectly lead to the destruction of foreign material (antibody-mediated immunity).
 - b. T lymphocytes (T cells) directly destroy virus-invaded cells and mutant cells by releasing chemicals that punch lethal holes in the victim cells (cell-mediated immunity).

A given leukocyte is present in the blood only transiently. Most leukocytes are out in the tissues, on defence missions. As a result, the immune system’s effector cells are widely dispersed throughout the body and can defend in any location.

LYMPHOID TISSUES

Almost all leukocytes originate from common precursor stem cells in the bone marrow and are subsequently released into the blood. The only exception is lymphocytes, which arise in part from lymphocyte colonies in various lymphoid tissues originally populated by cells derived from bone marrow (p. 446).

Lymphoid tissues, collectively, are the tissues that produce, store, or process lymphocytes. These include the bone marrow, lymph nodes, spleen, thymus, tonsils, adenoids, appendix, and aggregates of lymphoid tissue in the lining of the digestive tract called **Peyer’s patches** or **gut-associated lymphoid tissue (GALT)** (► Figure 11-2). Lymphoid tissues are strategically located to intercept invading microorganisms before they have a chance to spread very far. For example, lymphocytes populating the *tonsils* and *adenoids* are situated advantageously to respond to inhaled microbes, whereas microorganisms invading through the digestive system immediately encounter lymphocytes in the *appendix* and GALT. Potential pathogens that gain access to lymph are filtered through *lymph nodes*, where they are exposed

Check Your Understanding 11.2

1. Describe the epidermis, dermis, and hypodermis.
2. List and state the functions of the four resident cell types in the skin.

► **FIGURE 11-2 Lymphoid tissues.** The lymphoid tissues, which are dispersed throughout the body, produce, store, or process lymphocytes.

to lymphocytes as well as to macrophages that line lymphatic passageways. The *spleen*, the largest lymphoid tissue, performs immune functions on blood similar to those that lymph nodes perform on lymph. Through actions of its lymphocyte and macrophage population, the spleen clears microorganisms and other foreign matter from the blood that passes through it and also removes worn-out red blood cells. The *thymus* and *bone marrow* play important roles in processing T and B lymphocytes, respectively, to prepare them to carry out their specific immune strategies. ■ Table 11-1 summarizes the major functions of the various lymphoid tissues; some of these are described in Chapter 10 and others are discussed in Sections 11.5–11.7 of this chapter.

We now turn our attention to the two major components of the immune system's response to foreign invaders and other targets—the innate and the adaptive immune responses—and in the process further examine the roles of each type of leukocyte.

Immune responses

Protective immunity is conferred by the complementary actions of two separate but interdependent components of the immune system: the *innate immune system* and the *adaptive*,

■ **TABLE 11-1 Functions of Lymphoid Tissues**

Lymphoid Tissue	Function
Bone Marrow	Origin of all blood cells Site of maturational processing for B lymphocytes
Lymph Nodes, Tonsils, Adenoids, Appendix, Gut-Associated Lymphoid	Exchange lymphocytes with the lymph (remove, store, produce, and add them) Resident lymphocytes produce antibodies and sensitized T cells, which are released into the lymph.
Tissue	Resident macrophages remove microbes and other particulate debris from the lymph.
Spleen	Exchanges lymphocytes with the blood (removes, stores, produces, and adds them) Resident lymphocytes produce antibodies and sensitized T cells, which are released into the blood. Resident macrophages remove microbes and other particulate debris, most notably worn-out red blood cells, from the blood. Stores a small percentage of red blood cells, which can be added to the blood by splenic contraction as needed
Thymus	Site of maturational processing for T lymphocytes Secretes the hormone thymosin

or *acquired, immune system*. The responses of these two systems differ in timing and in the selectivity of the defence mechanisms.

The **innate immune system** encompasses the body's *non-specific* immune responses that come into play immediately on exposure to a threatening agent. These nonspecific responses are inherent (innate or built-in) defence mechanisms that nonselectively defend against foreign or abnormal material of any type, even on initial exposure to it. Such responses provide a first line of defence against a wide range of threats, including infectious agents, chemical irritants, and tissue injury from mechanical trauma and burns. Everyone is born with essentially the same innate immune-response mechanisms, although there are some subtle genetic differences. The **adaptive or acquired immune system**, in contrast, relies on *specific* immune responses selectively targeted against a particular foreign material to which the body has already been exposed and has had opportunity to prepare for making an attack that's discriminatively aimed at

this foreign material. The adaptive immune system thus takes considerably more time to mount an immune response and takes on specific foes. The innate and adaptive immune systems work in harmony to contain, then eliminate, harmful agents.

INNATE IMMUNE SYSTEM
